IT is a common experience that when the student enters his medical school he finds himself attracted to a special department of the curriculum, and this was early the case with Mr. Cecil R. C. Lyster, whose death, we regret, took place on the 26th inst., owing to his devotion, at the Middlesex Hospital, to the study of radio-therapeutics in its application to malignant disease. He had been in charge of this department for 17 years. Lyster followed closely the physical and chemical methods in constant evidence in the laboratory at Charing Cross Hospital Medical School, then under the direction of Mr. C. W. Heaton, a personal friend of Mr. Lyster's father. He was attracted particularly by spectroscopic methods of analysis, which, no doubt, ultimately led him to reflect on the possible application of radiations to disease. This study received a stimulus from Roentgen's discovery of the X rays produced by the Crookes tube. The study was extended by the introduction of radium. Lyster pursued his work uninterruptedly with remarkable earnestness and convinced of a successful issue, a consummation which would have brought great joy to his heart. Whatever the future of radiology may be, Lyster's name will count in the ranks of those devoted men, who, knowing full well the sacrifices involved, made a determined and splendid attempt to relieve suffering humanity from a terrible scourge. The mystery surrounding the fact that X rays and other emanations can set up an ugly pathological process, while at the same time they are employed presumably on scientific grounds to stop the progress of such a process, is in urgent need of study.

AT the Royal College of Physicians of London lectures will be delivered on Tuesdays and Thursdays, at 5 o'clock, as follows:—Milroy lectures: Dr. Aldo Castellani, Feb. 26th, March 2nd, 4th, "The Higher Fungi in Relation to Human Pathology." Goulstonian lectures: Dr. J. L. Birley, March 9th, 11th, 16th, "The Principles of Medical Science as Applied to Military Aviation." Lumleian lectures: Sir John Rose Bradford, March 18th, 23rd, 25th, "The Clinical Experiences of a Physician during the Campaign in France and Flanders, 1914–1919."

AT the Royal College of Surgeons of England a Hunterian lecture on the Late Surgery of Gunshot Wounds of the Chest will be delivered by Sir Berkeley Moynihan on Monday, Feb. 2nd, at 5 P.M. On the following Friday, at the same hour, Mr. V. Z. Cope will deliver a lecture on the Surgical Aspect of Dysentery, and on Monday, Feb. 9th, Mr. H. Tyrrell Gray has taken as his subject the Influence of Nerve Impulses on Gastro-intestinal Disorders. Mr. J. Sherren's Hunterian lecture on the Late Results of the Surgical Treatment of Chronic Ulcers of the Stomach and Duodenum follows on Wednesday, Feb. 11th, and on Feb. 13th, 16th, and 18th Mr. Walter G. Spencer delivers three lectures on the Historical Relationship between Experiments on Animals and the Development of Surgery.

A memorandum just issued by the Medical Women's Federation contains suggestions as to the duty of the State in the control of venereal disease, which were approved at a special general meeting of the Federation held last month. While admitting the urgency of the danger to the community from venereal disease, it is the Federation's considered opinion that the measures now being suggested for the stamping out of infection might prove neither prompt nor effective in their action, while radical measures of reform would show quick and cumulative results.

Corrigendum.—In the annotation on Passive Movements in THE LANCET of last week the sentence 14 lines from the top of the page should, of course, read: "Referees without special knowledge should *not* order ......" The context saves the accidental omission of the negative from giving rise to misunderstanding.

"THE LANCET" OF JAN. 3RD, 1920.

THE Manager will be obliged to readers who have not any further use for their copy of THE LANCET of the above date if they will kindly return it to him at 1, Bedford-street, Strand, W.C. 2. The postage on the number is one penny. He will be pleased to pay for copies returned.

MEDICAL PRACTICE IN BELGIUM DURING THE GERMAN INVASION.

(FROM OUR SPECIAL COMMISSIONER.)

II.[1]

THE Belgian National Committee in organising the system of relief established a special department to manage medical relief. This included the provision of drugs. It was the same with dispensing chemists as with medical practitioners; a very large proportion of the patients and customers who used to pay their doctors and pharmacists had been swept away by the German invasion. The few medical practitioners who dispensed medicine to their patients would receive a special indemnity. Seeing how very general the custom of dispensing drugs has been among British practitioners, the measures taken in Belgium are of more than local interest. First of all, it was decided that the cost would be reimbursed by the National Committee only if the medical prescriptions were limited to the small pharmacopœia drawn up by the different provincial committees, according to their local resources. Every prescription had to bear the name and address of the patient, the number of his medical card, and the signature of his doctor. It would be null and void if it went beyond the scope allowed or was presented to others than the duly appointed and recognised pharmacists.

A National System of Medical Relief.

When after a while the service was thoroughly organised and the resources available increased, the indemnity allowed to the medical practitioners was fixed at 75 centimes per month per family. Those practitioners, however, who did their own dispensing received 1 franc 75 centimes. Thus more was allowed for medicine than for medical advice. In the old club practice of England, when the subscription paid was generally 4*s.* per annum per member, it was calculated that 1*s.* out of the 4*s.* per member covered the cost of medicine. On Oct. 1st, 1918, the indemnity in Belgium was raised to 1 franc per month per family, and to 2 francs when the practitioner provided the medicine required. At the normal rate of exchange this would be equal in round figures to 9*s.* 6*d.* per annum per family for medical attendance and another 9*s.* 6*d.* for medicine. These, it is true, are war conditions, drawn up when there was great difficulty in obtaining drugs; but then, again, the local committees limited the prescriptions allowed to such drugs as were available. Extra sums were and still are allowed, for this service continues on a reduced though still on a large scale for special services, as, notably, for accouchements. The patient has the right to call in a doctor or a fully qualified midwife. In either case, the fee given is 15 francs; but if unusual difficulties arise—dystrophia, for instance—the midwife must call in medical assistance. In this case the doctor also receives 15 francs. Any medical attendance required, after nine days since the birth of the child, is considered as usual medical attendance and included in the terms of the annual contract. Among other special services for which a separate arrangement is made according to the circumstances are consultations with oculists, oto-rhino-laryngologists, urologists, dermatologists, and dentists. All such consultations are paid for apart from the usual indemnity and on a scale fixed according to the circumstances. Whenever possible the cost has been evenly divided between the Central and National Committee and the local Provincial Committees.

Immediate Aid for Urgent Need.

Of course, this great and national service only concerns the Belgian Doctors' and Pharmacists' Relief Fund in an indirect manner. It is very evident, however, that but for its existence a far larger number of Belgian doctors would have been reduced to the greatest distress. Also its effects could only be felt gradually, whereas when a village had been attacked, a surgery burnt down, a practice destroyed or at least temporarily suppressed, immediate assistance was urgently needed. Then it was that the funds subscribed and sent over from England were of the greatest use. There was no need to wait for an official inquiry, which is inevitably a slow process. The Belgian Committee for the Aid and Protection of Victimised Doctors and Pharmacists acted at once. Like major and minor surgery, they had two categories of victims. For the worst cases 700 francs were sent at once. In the minor cases the sum given was only 400 francs. Then a monthly pension was paid of various sums up to a maximum of 250 francs per month. With this allowance the medical men thus relieved were just able to exist, though some among them had as many as eight or nine children. Not one of them all ever complained, and some who had received funds from England gladly rendered whatever gratuitous medical service was needed in their neighbourhood. Thus the British Medical Relief Fund was of assistance, in some instances, to the Belgian people at large, as well as to the Belgian doctors, and the Belgian people are not ungrateful. In the schools the children are now taught that they must never forget what Great Britain and the United States of America did for Belgium during the Great War.

Though this excellent lesson is being taught on all sides and profound gratitude is felt, there is also a good deal of grumbling. Of the 600,000 families who had to depend on the National Committee and the contract system of medical aid it set up, only half have been able to resume the payment of their medical attendants. 300,000 families still continued, more than a year after the actual fighting had ceased, to depend on the public medical service established during the war. It is not surprising if there are signs of impatience, and that complaints are made because, for instance, raw materials do not come plentifully from England, so that the Belgian factories and mills may get to work again. Families and neighbours have drawn closer together than they ever were before the war, and strive to encourage and help each other. They are told to work and things will right themselves and be as they were before; but the older people feel that they will not live to see that day. A sense of weariness, of listlessness, has overcome some who suffered beyond endurance or are not strong enough to react. These events have worked out in such a manner as to greatly discourage the best elements of the population.

Unequal Distribution of the War Burden.

During the German occupation a very large portion of the working-class and of the industrial and commercial classes behaved with heroic patriotism. This may especially be said with regard to the railway servants. They preferred starvation and persecution to working for the Germans. Others, on the contrary, accepted employment from the enemy, and thus got food and wages. Manufacturers had their machinery respected, and some made large profits. Now that the country is free again, it is precisely this, the less patriotic section of the population, which to-day is best able to profit by the rebirth of industry. Those who, on the contrary, held out against the Germans, had their machinery destroyed or carried away, and so are not in a position to resume their former industry. The workmen, on their side, who refused to work for the Germans, are also hardly in a better position. More than four years' enforced idleness and underfeeding has destroyed much of their former energy and readiness to work. They have not strength; they long for rest and quietude. They do not want to be troubled; they are deeply depressed. If the cost of living was not so high, a few months of the desired freedom from care and fear, accompanied with a generous diet, would doubtless do much to restore the former efficacy of the Belgian workman, but this desirable solution of the difficulty is not yet possible. It will be very interesting to know what will be the moral and physical effect of the martyrdom of a whole nation. The most terrible fact is that those who behaved best have suffered most. They are therefore the least able to profit by the restoration now slowly taking place. To prevent this glaring injustice should be the first desire of every right-minded person; and, where there is the will, there should be a way.

ASSISTANCE TO VOLUNTARY HOSPITALS.

A RED CROSS SCHEME ADOPTED BY THE BRITISH HOSPITALS' ASSOCIATION AT A CONFERENCE ON JAN. 23RD.

THAT the voluntary hospitals of the country are passing through something not far short of a financial crisis is well known, and the reasons are not far to seek. In the first place the rise in the cost of staff, foodstuffs, drugs, dressings, linen, &c., during the last five years has been abnormal; and in the second place structural alterations, extension, repairs, and even the ordinary annual cleanings and renewals have had to be suspended during the war.

The financial shortage has been to some degree met by the wonderful generosity of the public, which seems almost inexhaustible, even in these days of high taxation and depreciated currency. But those who have to collect money for charitable purposes know that their appeals must now be made in a different way from that which sufficed before the war. In those days the benevolent assistance of a comparatively small number of subscribers answered the purpose. Now the appeal must be organised and made to the masses, who are ready enough to give, but who cannot afford to give large sums.

The Organised Collection of Small Donations.

It is only by the organised collection of small donations that the vast sum of money which is needed by the voluntary hospitals of the country can be raised, and it is to the solution of this problem that our attention must be turned.

During the war the Joint Committee of the British Red Cross Society and the Order of St. John was responsible for the establishment and maintenance—beyond the Government capitation grant—of some 1600 auxiliary hospitals. For this purpose a large sum of money had to be collected every year, and an organisation gradually arose which eventually became the greatest collecting agency in the country. "Our Day" has now become not only a national but an imperial institution, as the day on which the hearts of the countless millions of British subjects all over the world go out to those of their race who are sick and suffering. Surely this organisation can be of use in time of peace, as in time of war, and the sympathy of British people will be no less real for civilians who have fallen in the battle of life than it was for the gallant men who were wounded on the battlefield.

For many years the London hospitals have enjoyed the benefit of great collecting organisations, such as King Edward's Hospital Fund, the Hospital Sunday Fund, the Hospital Saturday Fund, and the League of Mercy. The provincial hospitals have no such central funds, and this fact suggests a useful field of work for the Red Cross organisation.

The Joint War Committee of the British Red Cross Society and the Order of St. John has practically finished its work, but it lives again in the form of a Joint Council, which desires to do for civilians work of a similar character to that which was done for soldiers and sailors during the past five years, and to act as a channel through which the generosity of the British public may flow to the relief of suffering and distress.

If the voluntary hospitals throughout the country will accept the assistance of the Red Cross, then assuredly the spirit of sympathy which made the war work of the Joint Committee possible will not be wanting for the equally important peace work of the Joint Council.

Help other than Financial.

There are many ways in which the Red Cross can help the voluntary hospitals in addition to the collection of money. The preparation of statistical tables similar to those issued by King Edward's Hospital Fund would be of the utmost use to hospitals by giving them the means of comparison with each other's figures, and thus detecting possible loss and waste.

Information and statistics could also be codified and tabulated at a central office in London, where there would be a reference library, to which application could be made for the latest details regarding all matters connected with hospitals, such as planning, construction, heating, lighting, &c.

Stores.—The Joint Council has storage accommodation in London, and proposes to invite gifts of hospital stores, &c., from which grants could be made to hospitals in need. In connexion with stores (especially the requirements of surgery and dispensary) it may be pointed out that the Council will be in a position to buy on the most advantageous terms under expert advice, and it is thought that in this way it would be of considerable use to those hospitals which desired to avail themselves of the opportunity, as the Red Cross undoubtedly was to many hospitals and to the Government itself during the war.

Buying on analysis.—At headquarters facilities would be provided for the analysis of articles of hospital consumption, and for the supply of details with regard to prices and deliveries of all hospital commodities. Here, also, if necessary, would be stored in bulk non-perishable drugs, dressings, &c., from which applicant hospitals might draw, should they so desire.

Work parties.—It is hoped that some at least of the work parties that did such valuable service during the war in providing the necessary hospital garments, &c., will be inclined to carry on their good work in time of peace. A circular is being addressed to the counties asking the work parties, as during the war, to provide first for the necessities of their own local hospitals, and then to send up to headquarters such surplus stock as may be available. If it were found that the response from the counties warranted it, a statement setting forth the particular articles of which the hospitals and child welfare centres were most in need would be issued from time to time.

War and peace library.—The War and Peace Hospitals Library, which has distributed such a vast number of books and magazines to military hospitals during the past five years, still remains in existence and is willing to carry on its work in peace time for the civilian hospitals. It is obvious that literature is just as much required by civilian patients in hospital as by sick and wounded sailors and soldiers, and it is earnestly hoped that the Red Cross organisations throughout the country will continue to give to the Library that unfailing and generous support which they have given during the past five years.

The Only Condition Attached to the Help.

These are some of the ways in which the Joint Council of the British Red Cross Society and the Order of St. John could help the provincial hospitals, and all that the hospitals would have to do in return would be to keep their accounts on the uniform system, which is unanimously accepted by the London hospitals and by most of the larger hospitals in the country.

This Memorandum does not pretend to enter into details, as these must be settled in consultation with the representatives of the hospitals themselves, should the scheme meet with acceptance. It must only be regarded as an outline of the way in which a great voluntary organisation might prove of assistance to voluntary hospitals. It is obvious that the money grants that could be made to hospitals must necessarily depend upon the measure of financial support received from the public by the Joint Council, but even if no large amount of money were forthcoming there would undoubtedly be much to be gained by the establishment of a central bureau where expert advice and statistical information could always be obtained, and where particulars of any branch of work in which an individual hospital excelled would be available for the use of other hospitals and for the benefit of the community in general.

January, 1920.

HOUSING NOTES.

The Problem of the Unfit House.

THE problem of the house unfit for human habitation is an ever-present one, accentuated only by recent events. An interesting aspect of the question is discussed in his annual report for 1918 by Dr. J. W. Hembrough, the county medical officer of health for Northumberland, whose death was recorded in our issue of last week. This report is, of course, founded on the general position of the last year of the war, when the difficulties of labour and cost could not be clearly anticipated. Dr. Hembrough points out the need, on the part of the local authorities concerned, of a definite policy for dealing with the 1500 houses or more in that county which are unfit for human habitation and incapable of being made fit. He points out the danger of postponing closing orders until the local housing scheme has been *completed*; for if the contemplated scheme prove insufficient or be incompletely carried out the unfit houses may continue to be occupied. Dr. Hembrough therefore suggests that closing orders should, as the building scheme progresses, be issued in the proportion that the number of unfit houses bears to the number of new houses in the council's scheme, so that the occupation of the unfit houses would terminate with the completion of the housing scheme. This is a wise and valuable suggestion. Its influence would probably extend beyond its immediate purpose of ensuring the closure of unfit houses, and would affect the primary problem—the decision as to whether a house shall, or shall not, be labelled as unfit for human habitation. Rightly or wrongly, there is little doubt that in some areas the number of houses so labelled has been limited by the doubt as to the likelihood of such action being made effective by closure under present conditions.

The decision as to whether a house is unfit or not has always been a matter bristling with difficulties. No clear-cut rule can be promulgated. Text-books tabulate lists of defects rendering a house unfit for occupation. The Ministry of Health has recently issued an admirable manual on the subject in which the general principles are clearly summarised. But the rub comes when for the arm-chair perusal of suggestions is substituted their practical application to a particular cottage. It is the experience of all that general standards as to fitness in housing need often remarkable adjustment in individual cases. The unsound house might almost be said to bear to the medical officer of health the same relation as does the sick patient to the private practitioner—text-books are indispensable, but the individual, whether house or patient, often will not square with the type. The ultimate question to be answered is not, "Is this house damp, or dark, or cramped?" but the much vaguer one, "Is this house liable through structural defect to affect the health of its occupants so adversely that it should not be occupied?" This standard, vague enough at any time, has of late been confused by several extraneous considerations. One has already been mentioned—the doubt as to whether the condemnation of a house could be made effective. Other cross-currents have also come into play. For instance, there is the idealist who sees in the present discontent a chance of creating a new heaven and a new earth by a wholesale destruction of the old. There is also the administrator who feels that in the face of present economic stress and high prices he must not produce still greater scarcity by condemning houses which under happier circumstances he would not allow to remain standing.

While probably most medical officers of health have managed to steer a clear course between the opposing policies, the experience of the past few months, now crystallised in the housing surveys of the various districts, is likely to show that in some areas the medical officer of health has been deflected to some extent from his course in this matter. This is, on the whole, most likely to apply to part-time officers in the smaller districts, where the conditions of appointment render the medical officer more susceptible than his whole-time colleague elsewhere to the views of members of his authority. All such deviations will doubtless right themselves in time. It is probable that in a number of areas more houses, at present classed as merely below a reasonable standard or as unfit but capable of being made fit, will definitely be condemned when it is realised that a methodical procedure, such as that suggested by Dr. Hembrough, for their closure will distribute the burden equitably, ensure effective closure, and remove many of the difficulties anticipated. It becomes increasingly clear that the only wise rule for the medical officer of health in his consideration of housing is to ignore all temporary economic and social vagaries, and to have regard solely to the relation of house to health. Only thus will he establish for himself a standard which will not be stultified in future years.

Official "Illegalities."

The housing department of the Ministry of Health has the unusual experience of being in the position of an examinee whose work has been "turned down." The Greenwich borough council is concerning itself with the conversion of 30 or 40 old houses into flats. The plans prepared for the council in the first place were not proceeded with, the Ministry's housing department being invited to carry the work through on its own lines. The medical officer for Greenwich now reports that the conversion has produced more flats than the laws of hygiene, and even the regulations of the Town Planning (1919) Act, will allow. He has recommended the borough council to reconstruct the buildings according to the original plans. The medical officer's report has been forwarded to the Ministry of Health.

The Shortage of Labour.

There has been little or no response to the Prime Minister's appeal for dilution of labour in the building trade and the shortage of bricklayers remains the most difficult factor in the housing problem. The official publication of the Ministry on the subject concerns itself more and more with methods of constructing houses. In the meantime an important experiment is being commenced in Manchester, where a Building Guild Committee has been formed. This committee claims to have a monopoly of the labour, and states, moreover, that through its agency alone the Manchester housing scheme can be carried into effect. The main idea is that if the industry is controlled by the workers themselves work will be given ungrudgingly and far more will be carried through than is possible by unwilling work done for a contractor. If the tender of this committee is accepted—and there seems no great likelihood of its being refused—the guild movement may spread.

Garden Cities.

It is satisfactory to note that the encouragement given by the Government to ideal town-planning has not been without effect. One of the most interesting schemes of this nature, because it is in a neighbourhood where ideal planning has been little seen until now, is the scheme for the Isle of Dogs. Here 120 houses are to be built, the whole scheme being estimated to cost £110,000, not including the price of the land, which is stated to have cost nearly £10,000. The mayor encouraged the builders by saying that there was no reason why they themselves should not occupy some of the finished houses.

The Renovation of Slums.

The last two numbers of *Housing* contain an account, under the title of "A Glasgow Housing Experiment," of the experience of that city in making "bad areas" healthy. The bad areas selected for treatment contained houses whose frameworks were sound but whose interiors were dilapidated and verminous. The inhabitants conformed closely to their environment, and the general atmosphere was one of disease and disorder. These areas are now "healthy and respectable working-class districts." The houses were all overhauled in the absence of their tenants—a happy condition not easy to achieve at the present time. Where lighting conditions were bad these were improved by rearrangement of interiors. The cost of these alterations was considerable and the difficulties in "renovating" the tenants were at least as great as those met with in their homes. But in the result faith and perseverance have been justified.

BRITISH FEDERATION OF MEDICAL AND ALLIED SOCIETIES:

DEPUTATION TO DR. ADDISON.

ON Jan. 23rd the Minister of Health received a deputation from the Federation of Medical and Allied Societies, which waited on him to give effect to the resolutions adopted at the Conference at Steinway Hall on Dec. 12th, 1919.[1] The deputation, which was introduced by Sir W. Watson Cheyne, M.P., and supported by Lieutenant-Colonel F. E. Fremantle, M.P., consisted of the following: Dr. Arthur Latham, Dr. E. H. Stancomb, Sir Thomas Horder, Dr. J. F. Gordon Dill, Dr. Charles Buttar, Dr. N. Howard Mummery, Mr. Frank Coke, Dr. R. H. Cole, Dr. Rashell Davison, Miss Eaton, Sir William Arbuthnot Lane, Bart., C.B., M.S., Sir Thomas Parkinson, M.D., Dr. William Pasteur, C.B., C.M.G., Dr. B. A. Richmond, Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., Mr. F. P. Rowsell, J.P., and Dr. Arthur Shadwell. The object was to represent to the Minister of Health that a public inquiry should be held as to the conditions of service under the National Insurance Medical Benefit, and as to how far those conditions promote efficiency on the part of the medical profession and give commensurate results to the community.

It was emphasised by Dr. Arthur Latham, Sir Thomas Horder, and Dr. Charles Buttar, speaking for the deputation, that the existing regulations do not permit the insured person to receive all that the science of medicine has to give, nor enable the medical practitioner engaged in panel service to do the effective work that he is able and anxious to do; that there exists widespread dissatisfaction with the working of the panel system both on the part of the insured and the panel practitioner; that the Act has now been in force seven years without any public inquiry having been made to ascertain its efficiency or inefficiency; that such an inquiry would seem to be a necessary preliminary to any expansion or alteration of the provisions of the Act; that the question of remuneration of panel practitioners, which has recently been a matter of negotiation between the Minister and the Insurance Acts Committee of the British Medical Association and which has now gone to arbitration, is of secondary importance to the question of efficiency; and that the Treasury grant for the purpose should be governed by the amount necessary to ensure a satisfactory service, and *not* be reviewed, as Dr. Addison on Jan. 14th, 1920, stated it would be, in the light of other national commitments. It was pointed out that upon the health of the workers depends the solution of industrial unrest, and that to continue an unpopular and apparently inefficient experiment in the medical treatment of a large proportion of the community is likely to increase that unrest.

Dr. Addison's Reply.

Dr. Addison, in replying to the deputation, admitted "that the present system was a chaos of effort, and that a public inquiry was likely to instruct the public, the doctors, and himself," but he held that he must await the report of his Consultative Council on the working of the present system before deciding to advise the Cabinet to set up a wider inquiry than the Council could undertake. He aimed "at a scheme whereby a markedly individualistic profession could work better together in the public interest." He also stated that he recognised and appreciated the work that the Federation had done and was doing, that he had always encouraged the movement, and regretted that the organisation of the allied professions in a political sense, as was now being achieved by the Federation, had not been begun 20 years ago.

---

[1] THE LANCET, Dec. 20th, 1919, p. 1160.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

A National Medical Service.

THE announcement that the Irish Public Health Council had decided to recommend to the Government the establishment of a National Medical Service with entry by competitive examination has roused much interest in the medical profession in Ireland. It is remembered, of course, that in making this recommendation the Council is following on the lines of the Viceregal Commission which reported in 1906. As the chairman of the present Council was one of the members of that Commission, this decision of the Council should cause no surprise. The report o the Viceregal Commission received a warm welcome both from the public and from the medical profession, and many of its recommendations have become part and parcel of the programme o reform put forward without ceasing by the medica profession in the past 12 years. It is to be hope that the Government of to-day will prove more alive to the necessity of reform than was the Govern ment which pigeon-holed the Viceregal Commissioner's report. The transformation of the dispensary medica service and the other public medical services o Ireland into a unified national service would make changes which one unacquainted with rural condition in Ireland can hardly realise. The medical officers of the dispensary service are rightly discontented with thei present lot. They are underpaid, they serve under almos intolerable conditions, they are subject to the petty tyranny of local boards of guardians, and there is n provision for promotion or transfer. As members of national service, with adequate salaries, satisfactory conditions as regards leave and pensions, and the righ to promotion for good work, they will take a wider view of the possibilities of their career. At present and fo many years past it is too true that the most ambitiou and promising of young Irish medical men sought career outside their native country. In the future on may hope to see their own land retain the services o the best and most capable. The mere establishmen of a National Medical Service will not, however, o itself do this, unless those who will be concerned i framing it take meticulous care that the conditions c the service are thoroughly attractive. In the firs place the scale of salaries must be adequate. I must be such as to compete with other offers ope to young medical men. At the present value o money this means that the initial figure must be good round sum. The members of the service must b assured of facilities for performing their professiona work. The auxiliary services—hospitals, consultations pathological examinations—must be readily accessibl and efficient. There must be proper provision for leave for study leave, for promotion, and for superannuatio If these matters are well thought out in a generou mood one may hope for a bright future in Irish medicine

The Reference to the Irish Medical Committee.

The Irish Public Health Council has asked the Iris Medical Committee to put forward its views as to th functions and duties to be entrusted to the medic officers of the proposed Irish Medical Service, and as t the classes of the community which would be entitle to medical attendance in connexion with that servic The Irish Medical Committee appointed representative to advance certain views, but it cannot in any wa bind the medical practitioners of Ireland until it get back in full the final views of the Irish Public Healt Council on the matter, and then, as arranged, it wi have to call the whole profession together, as it ha no authority of any kind to assent to any arrange ment until the profession is first put in possession of a the facts. There is in Ireland a good deal of differenc of opinion on the question of a medical service betwee the Poor-law medical officers and the panel doctor especially those in the large towns. Does the propose "Irish Medical Service" extend only to the Poor-la doctors, or does it embrace all the general practitioner oor-law and panel doctors? Is it a full-time or part- me service? Neither the Irish Medical Committee, ıe Irish Medical Association, nor any other body dares ıke the responsibility of settling such questions until the hole body of the profession concerned is first consulted. ı any case, the future of such arrangements is un- ertain. The elections of last week demonstrate that ıe Labour Party and those who are in favour of n Irish Republic are now established in control of ıunicipal administration in most of Ireland. They ill more than likely defy the sanctions and regulations the Local Government Board in their administrative ıpacity, and they will have control of some millions local funds.

The Term "Panel Doctor" in Ireland.

Under the Insurance Acts, Ireland, as is well known, as excluded from the whole system of medical enefit, but the term "panel doctor," nevertheless, used in a broad sense for any medical practitioner ho has to do professionally with, and is paid by, ıe insurance authorities. To a certain degree they ight be called "certifiers"—that is, they sign, after camination, that so-and-so is unfit for work. A certain ım of money is put aside by the insurance autho- ties for the payment of those who sign a document these authorities that they are prepared to act as certifiers." The sum is £8000, I am told, for Belfast, ıd it is divided equally among these recognised certifiers" according to the number of insured persons camined, and who send in certificates. Any person n sign a certificate in Ireland, which is accepted by e insurance authorities, but payment by the insurance ıthorities is made *alone* to those recognised in the way have explained, and they may be said to constitute a cognised "panel." Medical benefit exists in the case tuberculosis and of maternity benefit, and recently r the treatment of discharged soldiers.

Presentation to Sir John Byers.

At a complimentary dinner given by his colleagues on e visiting staff of the Royal Victoria Hospital, Belfast, Sir John Byers on the completion of his term of service, piece of plate engraved with their names was handed him by Professor J. A. Lindsay, who presided, and ıo ascribed to Sir John Byers's 37 years' service e establishment and organisation of the special partment for women. Sir John Byers became in 93 professor of midwifery and of diseases of women d children in the Queen's University, Belfast; he ıs for three years chairman of the medical staff of the yal Victoria Hospital, for long a member of its board management, and at various times on the building mmittee of the new hospital and on the executive mmittee of the King Edward VII. Memorial Building r X Ray and Vaccine Therapy. He was knighted 1906.

Tragic Death of Dr. G. A. Hicks, of Belfast.

Dr. George Adams Hicks, whose death occurred from pticæmia, due to a hæmolytic streptococcus, after an eration prick, was only 43 years of age. A native of unty Sligo, he studied at Queen's College, Belfast, aduating M.D. R.U.I. in 1904, and in 1912 he became a llow of the Edinburgh College of Surgeons. For a ne he was demonstrator of physiology in Queen's llege, Belfast. On the resignation of the late Dr. St. Clair Boyd, in 1906, he was appointed one of the rgeons of the Samaritan Hospital, Belfast, where he came an operator of great promise. He is survived a widow and a daughter, to whom the deepest mpathy is extended.

CARDIFF MEDICAL SOCIETY.—This society held a nical evening on Jan. 20th. Two cases of Talipes were own, one after and one before operative treatment, con- uent upon infantile paralysis, in girls aged 12 and 14 ars respectively; and a typical case of Pseudo-hypertrophic scular Paralysis in a lad was exhibited by Dr. Ivor vies.—Mr. A. Howell brought two cases of doubtful gnosis before the society, one in a male of a tumour parently attached to the crest of the right ilium; the ıer, in a woman, of unusual enlargement of liver and een not associated with definite blood changes.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Encephalitis Lethargica.

THE new disease, which seemed to be diminishing, appears to make fresh progress. Cases still occur in the Paris district, and have recently occurred also near Lille and Cherbourg, where several deaths have taken place. About 20 cases have been recorded. The disease causes anxiety, partly on account of the high mortality —1 in 4—but also because of our ignorance as to the method of infection. Its infectious nature is more or less established, since many cases have been reported from the same family or the same house. The respiratory passages are suspected, but nothing certain is known, even of the nature of the disease. M. Netter suggests a filterable virus, comparable to that of epidemic poliomyelitis or infantile paralysis, and that this is the same disease attacking the base of the brain instead of the spinal cord. The cerebro-spinal fluid is negative on examination. If signs of meningeal reaction are observed, according to M. Pierre Marie, the case is probably one of syphilitic or tuberculous meningitis. On the other hand, M. Achard thinks that the presence of white globules in the cerebro-spinal fluid does not exclude encephalitis lethargica. He thinks that in these cases there is a special localisation of influenza; some cases are certainly associated with pneumonia. The public are much agitated about this mysterious disease, and tend to attribute to its agency every case in which sleepiness is observed. Comic papers and music-halls have already adopted it as a topical allusion. The most characteristic signs up to the present are a temperature up to or even over 39° C., lassitude, a tendency to sleep prolonged over several days or even weeks, and ocular paralyses, including ptosis, strabismus, abolition of ocular reflexes, and paralytic changes involving even the facial or trigeminal nerves. According to M. Netter, the disease is not absolutely new, and can be identified in descriptions of former epidemics, especially those in 1712 and in 1890.

Kineplastic Amputations.

Dr. Tuffier has recently described to the Académie de Médecine his first attempts at applying the new method of treatment of amputation stumps recently initiated in Italy, where he has seen it performed. The method consists in preserving the greatest possible length of tendons, which, when covered with skin, are used individually to move different parts of the apparatus attached to the stump. Thus the fingers of an artificial hand can be moved, after an amputation at the wrist, by the flexor tendons, whose ends are folded back and sutured to form rings into which hooks attached to the fingers are inserted. The idea is certainly very ingenious and deserves to attract the attention of surgeons, above all now when so many cripples have great difficulty in following a trade even with the best artificial limbs on the market. Dr. Tuffier, however, after his first experiments, finds that the technique of the operations must be considerably improved before the method can fairly be judged by its results. Hitherto the results in the lower limb have been practically nil; though the quadriceps extensor is an extremely powerful muscle, the isolated tendon does not develop enough strength to lift an artificial leg. Better results were obtained in the hand, but only in a small proportion of the patients operated on. It was surprising to find that in order to procure the amount of flexion obtained by a muscular shortening of $1\frac{1}{2}$ cm. in the living subject, a displacement of 6 or 8 cm. of the tendon of the contracting muscle was required. It is not that the traction made is not powerful as measured by a dynamometer; it is the artificial members that are at fault, and their mechanism will have to be modified. For instance, the hand and the fingers can execute the required movements only when these movements demand no force. However, Dr. Tuffier has seen a workman who was able to pursue his trade of a joiner as skilfully as before being crippled. This case is unique up to the present, and merely serves to justify the hopes founded on the future of this interesting method when it is sufficiently improved in surgical technique and adaptation of apparatus.

Isolation of Influenza Patients.

M. Lesage has just put in a plea, based on information received in connexion with the recent epidemic of influenza in children's hospitals, for isolation of the patients, if only by cubicles. It is the surest means of avoiding the unfortunate results of promiscuous overcrowding, an undeniable factor in the spread of the disease itself and of its complications. For the rest, M. Lesage shows that, contrary to the opinion too often reiterated, infants at the breast are not immune to the disease. If an infant but rarely contracts influenza it is just because, by the nature of things, babies live a relatively isolated life; but if they come into contact with victims of influenza they are liable to attack just as adults are.

Prophylaxis against Dysentery introduced by Demobilised Soldiers.

Considering the number of demobilised men suffering from malaria and dysentery, and liable to communicate the infection to their neighbours, M. Barbary, of Nice, believes that prophylactic measures should help both the patient and the community. As to the former, the principal precautions include the tracing of infected persons and their subsequent free examination and treatment, preferably in connexion with the public dispensaries; whereas the community will be educated by means of circulars, notices, and lectures, as has already been attempted in the case of malaria. In fact, there have been created throughout France prophylactic centres to fight malaria, with medical inspectors whose duty is to follow up demobilised malarial soldiers and to organise prophylactic measures in their neighbourhood, since it has been proved that anopheles mosquitoes can live in France. This already existing organisation could at the same time be adapted to prophylaxis against dysentery, which is much more definitely contagious. The medical inspector would render valuable service in instructing the patient's friends how to prevent the spread of the disease by the proper disinfection of his excretions and their receptacles and of all soiled linen. These precautions are not always taken in ignorant country circles, and the promiscuous conditions in which peasants dwell together create a very favourable medium for the infection, if the doctor does not himself educate them on completely new lines. These measures are the more urgent, as there are at the moment in France a large number of demobilised soldiers who have contracted dysentery in Salonica or the East and who suffer from frequent relapses.

A General Confederation of Scientific Work.

An important event, which will have a marked effect in French and foreign scientific circles, took place on Jan. 16th at the Collège de France. On the motion of M. Charles Moureu, member of l'Académie des Sciences and of l'Académie de Médecine, and with the support of most eminent scientists, among whom were MM. Appell, Lacroise, Picard, Henneguy, a preliminary gathering of delegates of French scientific societies considered the possibility of founding a general Confederation of scientific work. The principal object of the Confederation would be the organisation of scientific research, and it would probably embrace many hundreds of societies and include some 20,000 associates.

Jan. 17th.

THE Minister of Health has promoted Dr. Richard J. Reece, C.B., to be a Senior Medical Officer of the Ministry.

THE Women's Coöperative Guild have issued a circular demanding the control of maternity centres by the local authority rather than by voluntary organisations and adequate representation of working women on committees controlling them. Further, they urge an increase in the number of maternity and infant welfare centres, the provision of a sufficient quantity of milk to all mothers, and of more maternity homes; also the immediate establishment of maternity committees, a service of home helps, a national midwifery service, and a free service of medical specialists.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

Administrative County of Essex.

WE presume that the annual report for 1918 is the last that will be written by Dr. John C. Thresh, as he has now retired from the office of medical officer o health for the county, and that Dr. W. A. Bullough, his successor, will be responsible for such reports in future. At the request of Dr. Bullough, Dr. Thresh gives in this his final report, an excellent résumé of the sanitary work done by the Essex County Council since its inauguration in 1888. This is an exceedingly interesting record, of which the county council and Dr. Thresh have good reason to be proud. Among other matters the following are considered: The provision of isolatio hospitals; the prevention of river pollution; water supplies; scavenging and excrement removal; offensive trades; housing of the working classes; sanitary staffs of the different districts in the county; bye-laws i force; school medical inspection; tuberculosis; treatment of venereal diseases; maternity and chil welfare; administration of the Food and Drugs Act and public health laboratory work.

The good work done by Dr. Thresh in connexion wit the water-supplies in Essex is too well known to requir comment. At one time or other he has studied th supply of practically every village in the county, an in this connexion has made thousands of analyses. I the present report, however, he issues a timely warning The existing sources of supply are being depleted. Th water travels so slowly through the sand-beds in th lower London tertiaries, and the outcrop of the sand an of the chalk beneath is so limited that water is no being pumped from the wells more quickly than i can be replaced. Consequently, the water-level i continuously falling, and the difficulty and expense c raising it increases. Some years ago Dr. Thres pointed out that exceedingly minute quantities of chlorin would, under certain conditions, destroy all harmf bacteria in water. This method of sterilisation is c course, adopted by a large number of water compani and by the Metropolitan Water Board. There are rive in Essex yielding water which can be so treated, an in Dr. Thresh's opinion, the time will come when thes waters will have to be utilised.

Dr. Thresh's views on the tuberculosis problem a interesting if somewhat gloomy. He expresses th opinion that at the present time the tuberculosis office in the county are chiefly engaged in doing work whic could be equally well done by the medical practitione who are receiving the pay for it from the insuran funds. The sanatoriums are doing work which coul in many cases, be better done by providing tuberculo families with sanitary houses in the country an supplying nursing and home care, the necessa medical attention being given by the local pract tioners. Hospitals for advanced cases and for cas requiring surgical treatment will always be necessar while open-air institutions for children in the early stag of tuberculosis will always be desirable, but other cas could, as a rule, be better and more economically dea with in their homes than in sanatoriums. It must admitted that sanatorium treatment on a large scale h not yet had a fair trial, and the results obtained so f as the experiment has extended are rendered of litt value on account of war conditions. But the fact th the disease has steadily increased since the Insuran Act was passed does not afford much ground for hop However much sanatoriums are improved, and howev unsuccessful the results, there will always be peop who will attempt to explain these results by allegi inefficient treatment or administration to be the caus To meet these views more and more money will be spe and one can only hope that ultimately there will results commensurate with the expenditure. The can be no question that children in the early sta of tuberculosis, and in the state of malnutrition whi renders them especially susceptible to the disease, are very greatly benefited by open-air treatment, but in many cases this improvement is only temporary, a return to home conditions gradually dissipating the energy they had acquired at the sanatorium. Dr. Thresh is, however, of opinion that on the whole the results in the case of children are more enduring than in the case of adults. With adults the institutional treatment has a distinct educational value, but the curative effect is too often neutralised by worry. Patients worry over their family affairs, they are in doubt as to what is going on at home during their absence, and often they worry, and very naturally, about the future. Something should be done to relieve them of such anxieties, a very difficult but most important problem towards which far more attention should be directed, since until it is solved sanatorium treatment can never be a real success. The State, having once taken charge of the consumptive, should, in Dr. Thresh's view, look after him in loco parentis until his health is fully restored or death has released him from his suffering. The present half measures cannot be expected to have more than a temporary effect, and it is to be hoped that the Ministry of Health will cause the fullest inquiries to be made with reference to the results obtained by the present system with the view of modifying it or supplementing it so as to secure more permanent benefit. We quite agree that, now that the war is over, some such inquiry as that suggested by Dr. Thresh is urgently required, and we hope that the Ministry of Health will lose no time in instituting it.

Having referred to the various sanitary developments in Essex during the last 29 years, Dr. Thresh goes on to compare the mortality statistics at the commencement of the period with those at the end of it, and in order to make the results more reliable he takes the averages for the five years 1890–94 and for 1914–18. This shows that the death-rate from all causes has fallen 18 per cent. The mortality among infants has fallen 37 per cent., whilst the infectious diseases—namely, scarlet fever, small-pox, diphtheria, typhoid fever, measles, and whooping-cough—have decreased no less than 70 per cent. Enteric fever has fallen 80 per cent. Pulmonary tuberculosis had decreased by 33 per cent. before the county campaign for its prevention had commenced, but since then it has increased and the fall now is only 14 per cent. Cancer has increased by 74 per cent. The statistics as a whole are very satisfactory. Had the death-rate for 1890–94 continued to the present time, the deaths in the present administrative county would have been 18 per cent. more than they are. In other words, there has been in recent years a saving of about 2600 lives per annum, and of these about 260 would be infants under 1 year of age. The deaths from infectious diseases have fallen to less than one-third of the previous rate, which is a very remarkable decrease. In Dr. Thresh's view the money spent in sanitary improvements during the last 30 years has been remunerative, and more than commensurate with the expenditure. We do not think anyone will disagree with him.

City of Birmingham.

In common with most other districts in the United Kingdom, Birmingham suffered from a severe epidemic of influenza during 1918, a brief account of which is given by Dr. John Robertson in his annual report for the year in question. The first epidemic wave of the disease commenced in the city in the middle of June, and had come to an end by the third week in July. For practical purposes it may be said to have lasted six weeks, the weather conditions during the period having been warm and dry. This wave was distinguished from the two that followed it by the great rapidity with which the disease spread over the whole of Birmingham, the number of persons attacked being larger than in the subsequent outbreaks. The onset of the malady was usually sudden and often alarming in character, and the accompanying prostration severe. The duration of the malady was short, most of the patients being able to resume work in four or five days. After the first wave had subsided there was an interval of ten weeks, during which few, if any, new cases occurred. Then, between the first week in October and the last week in December, there was a second epidemic wave of great virulence, attacking many of those who had escaped during the summer epidemic. The weather was at the time cold and for the most part dry. The symptoms were similar to those observed in connexion with the summer cases, but more severe in character. Some patients died of influenzal toxæmia in 24 to 48 hours. Many died of acute pneumonia, which, in the majority of cases, was of the nature of a confluent broncho-pneumonia, with some purulent bronchitis. No account is given in this report of the third epidemic wave of influenza in Birmingham, which, presumably, occurred in the early part of 1919. Dr. Robertson states that there appeared to be some evidence that an attack of influenza in June protected against an attack in November, but this was by no means absolute. There is no doubt that a large part of the whole population escaped the disease although frequently exposed to the infection—namely, doctors, nurses, and those looking after the sick. There is, therefore, sufficient evidence that not only does the natural immunity of individuals vary in degree, but also that acquired immunity varies in different individuals.

Among the preventive measures adopted in Birmingham may be mentioned the issue of handbills and the closure of kinemas, while the local press were most helpful in making known from day to day points which were thought to be of general importance. Extra visiting nurses were attached to the district nursing societies, and were found to be most valuable. Some hospital accommodation was made available in the general hospitals, in the union infirmaries, and in the City Hospital, Little Bromwich, for severe cases in which adequate nursing could not be obtained at home. During 1918 there were 2172 deaths directly attributable to influenza and in addition an excessive mortality from pneumonia of 256 deaths above the average. It is, indeed, safe to say that influenza was directly or indirectly the cause of at least 2500 deaths in Birmingham. That is, one out of every five deaths which occurred during the year was due to influenza. Had the disease not visited the city the death-rate would have been 12·4 instead of 15·2 per 1000 of the population.

Dr. Robertson's report also contains an interesting account of an inquiry into the ventilation of kinematograph theatres by Dr. W. H. Davison, assistant medical officer of health, and, in view of the widespread interest in this subject, Dr. Davison's conclusions and recommendations may be quoted. The conclusions are as follows:—

(1) The existing means of ventilation in a considerable number of kinematograph exhibitions is insufficient, and it is impossible to adequately ventilate buildings of this type by ducts in the roof unprovided with fans. It is only by the employment of fans that anything approaching adequate ventilation can be secured.

(2) Better ventilation could be secured in the majority of kinematograph exhibitions with the existing plant working regularly and efficiently. Interference with the fresh air inlets and failure to keep the ducts and fans clean contribute to the unsatisfactory results obtained.

(3) At present there is considerable delay in effecting the necessary repairs to the ventilating plant.

(4) The area of the fresh-air inlets is inadequate in many cases, and there is a tendency to close these openings.

(5) More satisfactory arrangements could be made for heating of fresh air supplied and the prevention of draught arising from the fresh-air inlets by placing the radiators in front of or under these openings.

(6) As regards lighting there does not appear to be any objection to the provision of windows provided they are properly screened.

The following recommendations are made:—

(1) That such a standard of ventilation be prescribed for the kinematograph exhibitions in the city that the proportion of carbonic acid in the air at about the breathing level should not rise beyond 20 volumes per 10,000 of air.

(2) That the space allowed per person should be fixed at a minimum of 120 cubic feet.

(3) That any defects in the fans or other means of ventilation should be reported immediately to the managers, and a book provided in which a record is kept stating the nature of the defect, when it was discovered, and steps taken to have the necessary repairs effected. This record to be available

for inspection by the justices on application for renewal of the licence.

(4) That all fans be tested either before or immediately on being placed in position, in order to ascertain their efficiency for the work they are required to do.

(5) That an automatic indicator, such as a coloured light, be fixed in a prominent position in the building indicating when the fans are working.

(6) That the fresh-air inlets be kept freely open, and that all means of regulating the size of these openings or of closing them be removed.

(7) That every house be provided with a thermometer.

(8) That the provision of windows and the position of entrance and exit doors be considered in relation to the flushing of the building with fresh air during intervals in the performance and during cleaning operations.

VITAL STATISTICS OF ENGLAND AND WALES FOR 1919.

THE following statement shows the birth- and death-rates and the rates of infant mortality in England and Wales, and in certain parts of the country, during the year 1919, the figures being provisional:—

—	Birth-rate per 1000 total population.	Civilian death-rate per 1000 civilian population (crude rate).	Deaths under 1 year per 1000 births.
England and Wales*	18·5	?	89
96 great towns, including London (populations exceeding 50,000 at the Census of 1911)	19·1	13·9	93
148 smaller towns (populations from 20,000 to 50,000 at the Census of 1911)	18·4	12·7	90
London	18·6	13·6	85

* The civilian death-rate for England and Wales cannot be stated at present, the number of non-civilian deaths in the fourth quarter of 1919 not being available.

VITAL STATISTICS OF LONDON DURING DECEMBER, 1919.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 10·7 per 1000 of the population, estimated at 4,026,901 persons; in the three preceding months the rates had been 6·6, 10·1, and 11·1 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in Kensington, Hammersmith, Fulham, St. Marylebone, Hampstead, and the City of London; and the highest in Finsbury, Bethnal Green, Lambeth, Deptford, Greenwich, and Lewisham. The prevalence of scarlet fever showed a slight decrease from that recorded in the preceding month; this disease was proportionally most prevalent in Chelsea, Islington, Finsbury, Southwark, Lambeth, Battersea, Greenwich, and Lewisham. The Metropolitan Asylums Hospitals contained 2841 scarlet fever patients at the end of the month, against 1633, 2293, and 2848 at the end of the three preceding months; the weekly admissions averaged 350, against 265, 340, and 427 in the three preceding months. Diphtheria was slightly more prevalent than in the preceding month, and the number of cases notified during December was higher than in any month of the last two years; the greatest proportional prevalence of this disease was recorded last month in Hammersmith, Hackney, Holborn, the City of London, Bethnal Green, Stepney, and Deptford. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1168, 1405, and 1572 at the end of the three preceding months, further rose to 1845 at the end of December; the weekly admissions averaged 239 against 180, 207, and 215 in the three preceding months. The prevalence of enteric fever was considerably less than in the preceding month; the 25 cases notified last month included 5 in Kensington, and 2 each in Paddington, St. Pancras, Hackney, and Woolwich. There were 25 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 49, 47, and 44 at the end of the three preceding months; the weekly admissions averaged 2, against 7, 6, and 5 in the three preceding months. Erysipelas was proportionally most prevalent in Finsbury, Shoreditch,

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING DECEMBER, 1919.

* Including membranous croup.

Bethnal Green, Southwark, Bermondsey, and Lambeth. Of the 11 cases of cerebro-spinal meningitis, 3 belonged to St. Pancras, 2 to Lewisham, and 2 to Woolwich; while the 4 cases of poliomyelitis belonged respectively to St. Pancras, Islington, Wandsworth, and Lewisham.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the five weeks ended Jan. 3rd, the deaths of 5462 London residents were registered, equal to an annual rate of 14·1 per 1000; in the three preceding months the rates had been 11·2, 14·1, and 14·6 per 1000. The death-rates ranged last month from 10·9 in Lewisham, 11·6 in Hammersmith, 11·6 in Wandsworth, 12·0 in Fulham, and 12·0 in Battersea, to 16·1 in Paddington, 16·2 in Southwark, 17·2 in Finsbury, 18·6 in Bermondsey, and 20·4 in Shoreditch. The 5462 deaths from all causes included 369 which were referred to the principal infectious diseases; of these 61 resulted from measles, 23 from scarlet fever, 145 from diphtheria, 58 from whooping-cough, 4 from enteric fever, and 78 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded last month in the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Kensington, Fulham, Chelsea, the City of Westminster, St. Marylebone, St. Pancras, Stoke Newington, and Wandsworth, and the highest in Hackney, Finsbury, Shoreditch, Bethnal Green, Bermondsey, and Deptford. The 61 deaths from measles were less than half the average number in the corresponding period of the five preceding years; this disease was proportionally most fatal last month in Finsbury, Shoreditch, Bermondsey, Lambeth, and Deptford. The 23 fatal cases of scarlet fever were 4 more than the average number, and included 6 in Islington, 3 in Lambeth, 3 in Deptford, 2 in Hackney, and 2 in Lewisham. The 145 deaths from diphtheria were nearly double the average; the greatest proportional mortality from this disease occurred in Hackney, Finsbury, Shoreditch, Bethnal Green, Deptford, and Greenwich. The 58 fatal cases of whooping-cough were equal to the average number; this disease was proportionally most fatal in Hammersmith, Bethnal Green, Stepney, Poplar, Southwark, and Bermondsey. Four deaths from enteric fever were registered during the month, against an average of 9. The 78 fatal cases of infantile diarrhœa were 26 below the average; the greatest proportional mortality from this disease occurred in Paddington, Hammersmith, Hackney, Finsbury, Bethnal Green, Poplar, and Camberwell. In conclusion, it may be stated that the aggregate mortality in London during December from these principal infectious diseases was 6·8 per cent. below the average.

(Week ended Jan. 24th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had been 16·2, 15·8, and 15·6 in the three preceding weeks, further declined to 15·3 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the annual death-rate was 15·1, or 0·7 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 5·1 in Aberdare, 7·1 in Gillingham, and 8·7 in Southend-on-Sea, to 24·1 in Grimsby, 25·0 in South Shields, and 27·5 in Carlisle. The principal epidemic diseases caused 351 deaths, which corresponded to an annual rate of 1·1 per 1000, and comprised 96 from measles, 84 from whooping-cough, 77 from diphtheria, 71 from infantile diarrhœa, 18 from scarlet fever, and 15 from enteric fever. Measles caused a death-rate of 1·5 in Preston, 2·0 in Dewsbury, 2·3 in Bootle, and 4·7 in Grimsby; and whooping-cough of 1·1 in Portsmouth, 1·6 in Birkenhead, 1·8 in Walsall, and 2·2 in Smethwick. The 85 deaths from influenza showed an increase of 23 compared with the previous week, and included 24 in London, 9 in Leeds, and 3 each in Birmingham, Manchester, and Newcastle-upon-Tyne. There were 2614 cases of scarlet fever and 1994 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2758 and 1945 respectively at the end of the previous week. The causes of 42 deaths in the 96 towns were uncertified, of which 7 were registered in Birmingham, 6 in Liverpool, and 3 each in Birkenhead and St. Helens.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at 2,400,000 persons, the annual rate of mortality, which had been 15·9, 16·6, and 16·1 in the three preceding weeks, fell to 15·3 per 1000. The 356 deaths in Glasgow corresponded to an annual rate of 16·7 per 1000, and included 6 from infantile diarrhœa, 4 from measles, 3 from diphtheria, and 1 each from enteric fever and whooping-cough. The 100 deaths in Edinburgh were equal to a rate of 15·3 per 1000, and included 2 from measles and 1 from diphtheria.

The Services.

ARMY PAY OF CIVILIAN MEDICAL PRACTITIONERS.

A ROYAL Warrant increases the rate of remuneration of civilian medical practitioners engaged under the Pay Warrant to render medical attendance and examine recruits where army medical practitioners are not available. The substituted rates for medical attendance (including vaccination and cost of medicines) are £7 10*s.* a year if there are fewer than 10 persons entitled to medical attendance, and when there are 10 persons or more £15 for every complete 25, or portion of 25, provided that the total emoluments for all services, exclusive of the examination of recruits, shall not in any instance exceed £1 10*s.* for any one day. The increase is in general on a 50 per cent. basis. For examination of recruits 2*s.* 6*d.* is allowed for each recruit for the Regular Forces, subject to a maximum of £2 a day for services under this head.

ARMY MEDICAL SERVICE.

Temp. Col. W. Hunter, C.B. (Captain, R.A.M.C., T.F.), relinquishes his temporary commission on reposting.

ROYAL ARMY MEDICAL CORPS.

The undermentioned to be acting Colonel: Major (acting Lieut.-Col.) G. W. Heron.

The undermentioned to be acting Lieutenant-Colonels: Major T. H. Scott; Capt. C. H. K. Smith; Temp. Capt. A. J. Blake.

The undermentioned relinquish the acting rank of Lieutenant-Colonel: Majors W. H. Forsyth, A. W. Gater, B. A. Odlum, R. B. Hole, W. I. Thompson, E. G. Ffrench, T. B. Unwin, O. Ievers; Majors and Bt. Lieut.-Cols. D. S. Skelton, M. G. Winder; Capts. A. J. Hickey, L. T. Poole, G. H. Stacke, W. D. Anderton.

Temp. Major W. E. Home to be acting Lieutenant-Colonel whilst commanding troops on a hospital ship.

Major and Bt. Lieut.-Col. D. S. Skelton is seconded for service under the Colonial Office.

Major J. E. H. Gatt retires on retired pay.

Major E. G. R. Lithgow is restored to the establishment.

Temp. Capt. (acting Major) W. M. Oakden relinquishes the pay and allowances of his acting rank.

The undermentioned relinquish the acting rank of Major: Capts. J. P. Litt, T. F. Kennedy, G. E. A. Argo, F. G. Flood, G. G. B. Holroyde, S. J. L. Lindeman, F. R. H. Mollan, H. W. Browne; Temp. Capts. R. B. Blair, H. B. G. Russell, R. A. Steven, R. W. S. Christmas, V. L. Connolly, W. C. Horton, R. Thomson, C. C. Harrison, A. Brown, A. M. Malcolmson, A. E. Quine, W. D. Cruickshank, R. S. S. Statham, C. N. Coad, A. Scott, F. C. Lees, W. Montgomery, S. J. W. Donald, F. De S. McMenamin, H. W. Turner, S. E. Picken.

Temp. Capt. R. Scott to be acting Major.

Capt. J. P. Quinn resigns his commission.

F. J. Waldmeier, late temporary Captain, and Temp. Lieut. S. P. Hyam to be temporary Captains.

H. P. Hodge to be temporary Lieutenant.

Officers relinquishing their commissions:—Temp. Lieut.-Cols. J. F. Haswell and H. J. Roberts (Lieutenant-Colonel, T.F. Reserve). Temporary Majors retaining the rank of Major: S. A. Smith (Major, Canadian A.M.C.) and J. A. Devine. Temp. Capt. W. N. Parker (granted rank of Lieutenant-Colonel). Temporary Captains granted the rank of Major: V. L. Connolly, W. D. Cruickshank, E. B. Gunson, I. Jones, C. N. Coad, C. E. Walker. Temporary Captains retaining the rank of Captain: T. Howell, E. U. Williams, S. J. Graham, J. B. Mason, J. A. Frost, R. J. Wilson, F. A. Kerr, J. S. Prentice, A. T. Gibb, J. R. Pate, R. G. Barlow, J. Campbell, O. G. Evans, H. F. Ferguson, R. J. B. Leney, G. H. Fraser, R. M. De Mowbray, S. C. W. Iredale, J. Hill, E. W. L. Sharp, W. Duffy, R. C. Hewitt, M. K. Robertson, G. C. Hartley, W. Gemmill, T. F. Ryan, C. A. D. Bryan, C. H. G. Lyall, R. H. Fletcher, H. G. Baynes.

GENERAL RESERVE OF OFFICERS.

Capt. F. E. Bissell (late Captain, R.A.M.C., Special Reserve) is granted the rank of Lieutenant-Colonel on ceasing to be employed.

SPECIAL RESERVE OF OFFICERS.

Capt. E. M. Cowell relinquishes the acting rank of Lieutenant-Colonel.

The undermentioned Captains relinquish the acting rank of Major: D. Dougal, K. K. Drury.

Captains relinquishing their commissions and granted the rank of Major: M. W. Ruthven, H. C. Rook, T. Lindsay, T. McEwen.

Captains relinquishing their commissions and retaining the rank of Captain: N. S. R. Lorraine, G. E. Shand, W. C. Davidson, J. C. A. McCalden, R. Stewart, F. Balkwill, T. G. James, J. R. Cox, H. E. Bamber, W. Feldman, G. H. Gidlow-Jackson, J. Taylor, R. F. Pinson, N. H. Harrison, J. Y. McLean, T. W. Wylie, R. A. Stewart, S. D. G. McEntire, P. MacCallum, J. R. John.

Lieut. R. Graham relinquishes his commission and retains the rank of Lieutenant.

TERRITORIAL FORCE.

Major (acting Col.) C. H. Lindsay, C.M.G., relinquishes the acting rank of Colonel on vacating the appointment of Assistant Director of Medical Services.

Capt. E. F. Buzzard, A.M.S., from 5th London General Hospital, to be Colonel.

Capts. (acting Lieut.-Cols.) O. W. D. Steel and C. H. J. Fagan relinquish the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

Capts. (acting Majors) C. G. Strachan and B. M. Footner relinquish the acting rank of Major on ceasing to be specially employed.

Capt. G. A. Williamson is seconded for service with the Aberdeen University Contingent, Senior Division, O.T.C., and is appointed to command the Unit.

Capt. A. Mitchell is seconded.

2nd London Sanitary Company: Capt. H. Jessop relinquishes his commission and retains the rank of Captain. Lieut. A. S. Reeves to be Captain.

1st Eastern General Hospital: Major H. B. Roderick is seconded for service with the Cambridge University Contingent (Medical Unit), Senior Division, O.T.C.

2nd South-Western Mounted Brigade Field Ambulance: Capt. (temp. Major) J. M. Dupont relinquishes the temporary rank of Major on ceasing to be specially employed.

3rd Southern General Hospital: Capt. (acting Major) R. Ritson relinquishes the acting rank of Major on ceasing to be specially employed, and is restored to the establishment.

2nd Western General Hospital: Major (acting Lieut.-Col.) A. Wilson relinquishes the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

Supernumerary for Service with the Officers' Training Corps: F. C. Purser (Major in Army) to be Captain for service with Medical Unit, Royal College of Surgeons, Ireland, O.T.C.

ROYAL AIR FORCE.

Medical Branch.—Flight Lieut. J. E. Dunbar (Captain, R.A.M.C., T.F.) relinquishes his temporary R.A.F. commission on return to Army duty.

Capt. J. Paxton and Lieut. (acting Capt.) C. Duggan are transferred to the unemployed list.

Dental Branch.—D. Blair is granted a temporary commission as Flight Lieutenant.

INDIAN MEDICAL SERVICE.

Captain to be Major: J. B. Hanafin. Captains to be temporary Majors: J. R. D. Webb, R. B. Nicholson, W. R. Stewart. Temporary Lieutenants to be temporary Captains: A. M. V. Hesterlow, Jatindra Mohan Mukharji, Balbir Singh, Sukumar Sanyal, Oyitti Churia Madhavan, Gopal Narayan Khanna, Bhuthapuri Thevapperumal Krishnan, Indra Narayan Sen Gupta, Mervanji Dinshah Printer, Shankar Ganesh Chavan, Periyatan Katinjippally Raman Nambiar, Kesheo Ganesh Mohile, Amulya Chandra Roy, Valente de Souza, Narayana Subrahmania Aiyar, Brij Ratan Jain, Chandrian Krishna Row, Ganesh Dattatraya Apte, Pandipeddi Kutumbiah, Coimbatore Sivaramkrishna Suryanarayan Sarma, Bamanji Pestanji Daruwala, Gautam Kumar, Chenji Krishnaswami Pillay, Prabodh Nath Bagchi, Kailashnath Waghray, Dhirendra Chandra Mazumdar, Jagan Nath Goil, Sahibzada Ahmed Khan, Mangalore Subha Rao, Kali Sahai Nigam, E. Nissim.

THE HONOURS LIST.

THE following awards to medical officers, for gallantry and devotion to duty in the places mentioned, are announced:—

C.B.E.

Major (temp. Col.) J. T. Clarke, C.A.M.C. (Siberia).

Military Cross.

Capt. James Vallance, R.A.M.C. (North Russia).

For great gallantry and devotion to duty in dressing and attending wounded under fire. As each objective was gained he followed up immediately, dressing and bringing in all wounded on his way. In one village the Bolsheviks landed a party of sailors, and it was only through his untiring efforts that the wounded were removed to a place of safety.

Temp. Asst. Surg. James Michael Connor, I.M.D. (India).

For marked gallantry and devotion to duty at Barley Hill Piquet on July 18th, 1919. He went out from Fort Maude, and, after being wounded himself, attended the wounded under fire until they were evacuated. He was again wounded while leaving, but continued at duty at Fort Maude until the 20th.

BROUGHT TO NOTICE.

The names of the following members of the I.M.S. have been brought to the notice of the Secretary of State for War for valuable services rendered in India during the war:—Lt.-Col. H. Boulton; Lt.-Col. (temp. Col.) H. Burden, C.I.E.; Capt. J. B. Hanafin; Maj. (acting Lt.-Col.) J. B. D. Hunter; Capt. J. A. A. Kernahan; Capt. (temp. Lt.-Col.) J. V. Macdonald; Temp. Lt. L. J. P. Mordaunt; Capt. R. R. M. Porter; Capt. J. A. Sinton, V.C.; Temp. Lt. Mahomed Nawaz; Capt. (temp. Maj.) M. A. Rahman.

And the name of the following member of the Canadian A.M.C. for valuable and distinguished services rendered in connexion with military operations in Siberia:—Maj. (temp. Col.) J. T. Clarke.

FOREIGN DECORATIONS.

American.

Distinguished Service Medal.—Hon. Maj.-Gen. Sir A. A. Bowlby, Kt., K.C.B., K.C.M.G., K.C.V.O.; Temp. Maj.-Gen. Sir R. Jones, Kt., K.B.E., C.B., T.D., A.M.S.; Maj.-Gen. Sir H. N. Thompson, K.C.M.G., C.B., D.S.O., late R.A.M.C.; Hon. Maj.-Gen. Sir C. S. Wallace, K.C.M.G., C.B., late R.A.M.C.

Egyptian.

Order of the Nile.—3rd Class: Lt.-Col. C. H. Anderson, M.C., Austr. A.M.C.; Maj. and Bt. Lt.-Col. (acting Lt.-Col.) H. V. Bagshawe, C.B.E., D.S.O., R.A.M.C.; Capt. (acting Lt.-Col.) H. S. Beadles, R.A.M.C. (T.F.); Maj. (acting Lt.-Col.) A. G. Coullie, I.M.S.; Lt.-Col. (temp. Col.) T. H. Forrest, D.S.O., R.A.M.C. (T.F.); Maj. (acting Lt.-Col.) G. W. Heron, D.S.O., O.B.E., R.A.M.C.; Maj. A. W. Moore, O.B.E., R.A.M.C. (T.F.); Lt.-Col. P. S. Lelean, C.B., R.A.M.C. *4th Class:* Maj. L. A. Avery, D.S.O., R.A.M.C. (T.F.); Capt. A. L. Sheppard, I.M.S.

French.

Légion d'Honneur.—Officier: Col. J. C. B. Statham, C.M.G., C.B.E., late R.A.M.C. *Chevalier:* Lt.-Col. R. de L. Harwood, C.A.M.C.

Croix de Guerre.—Capt. (acting Maj.) J. C. Sproule, R.A.M.C.

Ordre du Mérite Agricole.—Chevalier: Capt. J. Clayton, R.A.M.C. (T.F.); Capt. J. D. Davidson, R.A.M.C. (T.F.); J. Golding, D.S.O., R.A.M.C. (T.F.).

Hellenic.

Order of the Redeemer.—Chevalier: Capt. W. L. Murphy, R.A.M.C. (T.F.). *Officer:* Surg.-Cdr. R. W. B. Hall, R.N.

Greek Medal for Military Merit.—3rd Class: Temp. Capt. (acting Maj.) P. M. Heath, R.A.M.C.; Temp. Capt. (acting Maj.) R. Scott, R.A.M.C.; Capt. H. E. Smith, R.A.M.C. (T.F.); Temp. Maj. J. H. Spencer, R.A.M.C.; Lt.-Col. A. D. Waring, R.A.M.C. *4th Class:* Temp. Capt. R. E. G. Gray, R.A.M.C.; Capt. J. Ratcliffe, R.A.M.C. (S.R.); Temp. Capt. C. S. Thomson, R.A.M.C.

Hedjaz.

Order of El Nahda.—3rd Class: Capt. and Bt. Maj. (acting Maj.) W. E. Marshall, M.C., R.A.M.C.

Persian.

Order of the Lion and Sun.—3rd Class: Capt. C. J. Stocker, M.C., I.M.S.

Portuguese.

Military Order of Avis.—Commander: Temp. Lt.-Col. G. H. Usmar, O.B.E., S. Afr. M.C. *Chevalier:* Capt. F. B. Smith, M.C., R.A.M.C. (T.F.).

Serbian.

Order of St. Sava.—5th Class: Lt. (temp. Capt.) A. G. Harsant, R.A.M.C. (S.R.); Temp. Capt. (acting Maj.) W. H. Peacock, R.A.M.C.; Capt. J. Steedman, R.A.M.C. (T.F.); Temp. Capt. (acting Maj.) N. B. Stewart, R.A.M.C.; Temp. Capt. (acting Maj.) W. H. Welsh, R.A.M.C.

Gold Medal for Zealous Service.—Capt. P. H. Mitchiner, R.A.M.C. (T.F.).

Siamese.

Order of the White Elephant.—3rd Class: Capt. and Bt. Maj. R. C. Dun, R.A.M.C. (T.F.); Lt.-Col. R. de L. Harwood, C.A.M.C.; Maj. (acting Lt.-Col.) R. C. Wilson, R.A.M.C.; Lt.-Col. and Bt. Col. Sir E. S. Worthington, K.C.V.O., C.B. *4th Class:* Capt. J. H. A. Paquette, C.A.M.C.

Order of the Crown of Siam.—2nd Class: Lt.-Col. H. P. W. Barrow, C.M.G., O.B.E., D.S.O., R.A.M.C.

THE Lord Mayor will preside at a meeting at the Mansion House on Thursday next, Feb. 5th, at 3.30 P.M., when the Society for the Prevention of Venereal Disease will lay the importance of immediate self-disinfection as a means of preventing the spread of venereal diseases before the City of London. The speakers will include the Lord Mayor, Lord Willoughby de Broke, Lord Riddell, Sir William Arbuthnot Lane, Sir James Crichton-Browne, Sir Ray Lankester, Sir Archdall Reid, and Sir Arthur Sloggett.

THE LATE MR. G. R. GREEN.—George Richard Green, M.R.C.P. Edin. and M.R.C.S. Eng., who died of pneumonia at Portmadoc on Jan. 7th at the age of 61, was educated at Guy's Hospital, qualifying in 1882. Formerly he practised at Ripon and was medical officer of health to the urban district council, honorary surgeon to the cottage hospital, and medical officer to the training college in that city. During the war he had been commandant of the Portmadoc and Criccieth V.A.D.

HIGHER QUALIFICATION IN OPHTHALMOLOGY.

To the Editor of THE LANCET.

SIR,—In connexion with the interesting article in your issue of Dec. 6th last anent a higher qualification in ophthalmology, I may state that the Royal Faculty of Physicians and Surgeons of Glasgow has for very many years included ophthalmology as one of the subjects of examination for its Fellowship, and at present there is a proposal even further to strengthen the position of ophthalmology as a subject of special examination. Many years ago in the *British Medical Journal* I called attention to what seemed to me a suitable course for ophthalmic surgeons; and more recently, through the great courtesy of the Edinburgh Pathological Club, I have had an opportunity of re-stating these views, and also made a communication on the subject to the *Ophthalmic Review* in 1916. It has always seemed to me an extraordinary thing that some ophthalmic hospitals should require the senior members of their staff to have spent a great deal of time in the study of anatomy and physiology, which subjects they will forget within a year of their having passed the examination, for the simple reason that they do not form part of their everyday work, and at the same time appoint men on the staff of such hospitals who have never been within the doors of a physical laboratory. Unless a man has a fair working knowledge of trigonometry, of logarithmic arithmetic, and of plane rectangular coördinates, he cannot even read the best books on ophthalmic work. These subjects, no doubt, only concern one part, but a very important part, of ophthalmic practice. In addition to the time passed in a physical laboratory, there should be a considerable amount of time spent in a bacteriological laboratory; for, as I pointed out so far back as 1891, nobody should operate on an eye, except in extreme emergency, without a thorough-going bacteriological investigation of the conjunctiva.—I am, Sir, yours faithfully,

FREELAND FERGUS,
President, Royal Faculty of Physicians and Surgeons,
Jan. 15th, 1920. Glasgow.

THE PREVENTION OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—The attention of the Society for the Prevention of Venereal Disease has been drawn to a statement recently issued by the general secretary of the National Council for Combating Venereal Disease, which has been published broadcast. The National Council have a perfect right to their own opinions, although most experienced persons will not agree that education as to cause and result of disease, together with treatment, has ever been efficacious in stopping disease, unless accompanied by instructions in regard to prevention.

The National Council, again, insist on local cleanliness, but forget to mention that such local cleanliness is best obtained by the use of antiseptics. They again bring forward the old Australian statistics as evidence that immediate self-disinfection is not efficient. The high incidence of venereal disease among the Australian Forces in the field was due to the fact that only 10 per cent. of the men were supplied with the proper disinfectants and instructions for their use. Wherever immediate self-disinfection was properly applied, venereal disease was practically eliminated.

The National Council proceed to state that the almost unanimous majority of medical officers of health and clinic officers throughout the country are opposed to immediate self-disinfection. Our Grand Committee contains the names of medical officers of health of at least as high standing as those associated with the National Council.

In the next sentence of their statement the National Council compare unfavourably the experience of members of our Society with those of the National Council in regard to prevention and treatment of venereal disease. This is an unfortunate statement for the National Council to have made. We suggest that it would be advisable for the National Council to study the list of our Grand Committee with a little more care, before venturing to suggest that the weight of experienced medical opinion is against us.

The final sentence of the National Council's statement is as incorrect as all the others, for our Society has repeatedly affirmed the importance of other methods of prevention of venereal disease, besides immediate self-disinfection, but has pointed out that moral education takes a generation before its effects are produced, and that in the meantime something must be done at once to check the spread of these diseases.

We are, Sir, yours faithfully,

(Signed) WILLOUGHBY DE BROKE (President),

IS THERE A PARA-SCARLET FEVER?

To the Editor of THE LANCET.

SIR,—Certain characteristics of the present epidemic of scarlet fever again raise doubts whether two separate forms of the disease are not confused under a common designation. During the past few months two facts have been noticeable with regard to cases admitted as scarlet fever to the London Fever Hospital. First, the unusual number of relapses in hospital; and second, the number of patients giving a history of what appears to have been a previous undoubted attack of the disease. Most of the cases admitted have been of a benign type and complications have been the exception, although peeled tongue and desquamation have been the rule. On the other hand, there have been a few cases of undoubted septic or malignant character.

One may say at once that none of the milder cases alluded to are German measles; of this I am certain. In these mild cases the rashes have been scarlatiniform from the beginning, and indistinguishable from those which we consider characteristic of scarlet fever, although perhaps more fugitive than usual. Vomiting as an initial symptom has often been absent, pyrexia slight or moderate, the faucial inflammation not severe, tonsillar exudate often absent, and submaxillary adenitis uncommon. Albuminuria, too, has been exceptional. Rather a striking feature has been the unusual number of patients with moderate enlargement of the glands of the posterior triangles of the neck, the axillæ, and the groins.

It will at once be recognised that although the seasonal incidence is different and the tongue has peeled, the clinical characteristics of these mild cases closely conform to those described by Dukes as characteristic of his Fourth Disease—a disease which he considers distinct from scarlet fever, on the one hand, and from German measles on the other. It is, however, plain that these mild cases show a much greater affinity to true scarlet fever than they do to German measles, and the belief has gradually grown up in my own mind that we are dealing with a disease which is related to scarlet fever in the same way that paratyphoid is related to typhoid. Until bacteriological advance renders it possible, such a contention remains a mere hypothesis, but clinical observation of the types of case at present admitted to our scarlet fever wards has led me to suspect strongly that there are two types of scarlet fever, and that they are not mutually protective. It will be interesting to hear what has been the experience of others who have had to deal with the present outbreak. I am, Sir, yours faithfully,

Devonshire-place, W., Jan. 24th, 1920. CHARLES R. BOX.

REINFECTION IN TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—Doubtless all are in sympathy with Dr. Batty Shaw in doing the utmost for the liberty and comfort of the consumptive, but all cannot agree with him in basing a prejudice against the theory of reinfection on such sympathy. Dr. Shaw admits (THE LANCET, Jan. 24th, p. 180) that "it remains a fact that children are universally infected by the tubercle bacillus of the human form." If, then, the sources of infection are so abundant, and if infection is so common that all are infected in childhood, by what new law or new circumstance does reinfection become excluded? Unless a new factor of immense and far-reaching power can be shown to exist, is it not unreasonable to exclude reinfection as of ordinary and frequent occurrence? Nor does the theory or fact of auto-infection affect the question; for if the supposed immunising effect of one focus of infection does not protect from reinfection by bacilli from that focus, how can such supposed immunising effect protect from reinfection from without?

It is difficult to understand the pessimism of the hour, a pessimism that loosens our hold on ascertained facts, in order to launch us once again into a sea of uncertainties. May we not suppose that Dr. Shaw himself recommends patients for sanatorium treatment, warns them against spreading infection, and even warns relations? We all know that by these measures we are doing good, and not harm. Until reinfection is disproved (and the onus of proof rests with the opponents of the theory), surely notification must continue, and the elementary precautions usually enjoined must be followed. At the same time, such aids as the adoption of anti-catarrhal measures will be welcomed. When will the purifying of the atmosphere of our cities become a practical question with our public health authorities?

I am, Sir, yours faithfully,

London, Jan. 26th, 1920. R. M. FENN.

THE MEANING OF TACHYCARDIA.

To the Editor of THE LANCET.

SIR,—I have read with interest the article by Dr. McNair Wilson under the above heading in THE LANCET of Jan. 17th. Tachycardia is a comprehensive term, and the writer admittedly does not deal with the condition in all its aspects or with its origin from all known causes, but with the instability of heart which is frequently observed after various enfeebling ailments and some enfeebling circumstances not infective.

It is not my intention at the moment to question the persistence or otherwise of the toxins to which some such enfeeblements may be assumed to be due, but to welcome the evidence afforded by this article of a recognition of the importance of the neural factor in such conditions. It is not long since some who regarded themselves as specially enlightened exponents of cardiology would have treated the matter with little reference to the innervation of the heart. The "excitatory system" would have been found fully capable of accounting for all the phenomena in question irrespective of any nervous endowment, which was, indeed, usually denied it because such had not been demonstrated. Even the sinu-auricular node, however, —the "pace-maker"—has now been shown to be fully innervated, although modesty forbids my indicating the reference more particularly! There is also some experimental evidence that the "pace-maker" is preponderantly endowed by the right and the auriculo-ventricular node and bundle by the left pneumo-gastric nerve and, of course, also by the sympathetic.

But there is another point which also interests me in this article, inasmuch as it appears to be regarded as novel—namely, the view that cardiac acceleration following vagus depression, irritability, or atony is compensatory. Reference is, certainly, made to a recent contribution of Professor F. A. Bainbridge, in which it is remarked "that acceleration of the pulse can compensate for lessened contractile power in maintaining the output of the heart per minute," a conclusion, I presume, which Professor Bainbridge in no way desires to be regarded as original or novel. I think the impression must be general that this is a venerable commonplace of physiology. In any case it has for long and frequently been impressed on the clinician, and putting aside the less acute enfeeblements with which Dr. Wilson deals, is observed in a very demonstrable manner in the more serious phenomena associated with cardiac failure in angina pectoris. In this connexion I have myself termed the state which usually follows the shock of cardiac pain (if I may be permitted to regard the pain as cardiac) as a "rescuing augmentation and acceleration of the heart's beat."[1] Indeed, the now hoary and usually beneficent experience of the acceleration produced by the nitrites in such cases declares the compensatory nature of tachycardia under these circumstances.

In the cases to which Dr. Wilson refers he will, however, agree that the sooner tachycardia ceases the better will it be for the patient, and that the most efficient remedies are not so much drugs as the posture and relief from activity which reduce heart rate—namely, resting and the employment of such means as will remove the cardiac enfeeblement of which tachycardia is the expression and the rescuing effort.

I am, Sir, yours faithfully,

ALEXANDER BLACKHALL-MORISON.

London, Jan. 19th, 1920.

A PROFESSOR OF MILITARY MEDICAL HISTORY FOR OUR INDIAN WARS.

To the Editor of THE LANCET.

SIR,—We have had during our tenure of India unceasing wars all over that country, and in each case much loss of life has occurred. If one tries to trace out the history of the Indian Medical Service and the part they took with the British Army Medical Service it is exceedingly difficult to find any historic books from which officers could learn to benefit by our failures and obtain fuller instructions when such campaigns recur.

I would propose that a medical officer of the Indian Army be appointed as a "Historian of the Indian Medical Service" in peace and war, and of the British troops who fought side by side with them in the endless Indian wars. Such an officer would be a member of the headquarters staff of the army in India, and would deliver each year a course of instruction on medical war history in various parts of the continent of India.

I am, Sir, yours faithfully,

GEORGE J. H. EVATT, Major-General,

British Army Medical Staff, retired.

Junior United Service Club, Jan. 16th, 1920.

THE VERMIN REPRESSION SOCIETY.

To the Editor of THE LANCET.

SIR,—I note with very great satisfaction that in your issue of Jan. 17th you give prominence to the fact that the Government representative, at the Vermin Repression Society's dinner, pointed out that the Vermin Repression Society was only at the beginning of its work. As the society is just about to be incorporated under special licence of the Board of Trade and it has correspondents in Burmah, Egypt, India, and Australia, and also it has the flourishing section in Bristol, I think the time will not be far distant when its original founder and honorary organiser, Lieutenant Alfred E. Moore, the British Emil Zuschlag, will be caricatured as "The Modern Rat Robespierre"; for it cannot be too well known that it is owing to Lieutenant Moore, who initiated the movement against the rat in 1907, and who has never ceased, in season and out of season, to organise against the rat, that the present success is due, and that he refuses to accept a

---

[1] The Nervous System and Visceral Diseases, Edin., 1899, p. 98.

British rat law as being the culminating effort of his work, for he confided in me, after the dinner, that he would not be satisfied until the campaign against rats was properly organised on an international basis, as he believes that the whole future of medicine is bound up in verminological research and adequate vermin repression as a bulwark against disease.

I am, Sir, yours faithfully,
H. MILLS,
St. Margarets-on-Thames, Jan. 20th, 1920. Captain.

CHESHIRE LOCAL MEDICAL AND PANEL COMMITTEE.

[*To the Editor of* THE LANCET.

SIR,—I am directed by my Committee to forward for your information the following resolution, passed unanimously at a full meeting of my Committee at Crewe, on Saturday last :—

(i.) That this Committee expresses its most emphatic disapproval of the remuneration offered by the Government; and regrets that the I.A.C. thought fit to exercise its authorisation to ask for arbitration when the Government's offer proved to be such a low figure as 11*s*. (ii.) This Committee notes with especial regret that the terms of service for which the remuneration is offered are "the proposed Medical Benefit Regulations, 1920, as published in December last" which regulations (*a*) retain the provision by which the Minister may be at one and the same time the accuser or complainant, and the judge or arbitrator (Regulation 57), the accused having no appeal—a provision which in the opinion of this Committee is contrary to the spirit of English law; and (*b*) introduce a new provision [16 (c)], detrimental to the transfer of practices, which greatly diminishes their capital value; and (*c*) impose a new obligation on practitioners [First Schedule, Part 1, 5 (*c*) and Model Allocation Scheme 5 (i.) and (ii.)], requiring them to attend any insured person on the list of another doctor in an accident or sudden emergency if that doctor be not at the moment available, for a fee to be deducted from that doctor's remuneration.

With regard to (*b*) the Committee remarks that at the death of a doctor it is too often found that the goodwill of the practice is the chief and often the only asset which he has to leave to his widow and children, and that by this regulation this asset is, without compensation, greatly diminished, or it may be abolished. With regard to (*c*) a trying and uncertain and entirely new duty is imposed on a panel doctor *in the shape of a legal obligation*. When has it happened, the Committee asks, in the past that doctors have ignored the claims of urgent illness? They have voluntarily dealt with such cases as they occurred on their merits. They resent, however, being *legally obliged* to attend all and any who may demand their services on a plea of urgency; and they note that the reality or otherwise of the urgency is left to the decision of the patient.

I am, Sir, yours faithfully,
LIONEL JAS. PICTON,
Jan. 21st, 1920. Hon. Secretary.

CAUSE OF DEATH CERTIFICATION.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Jan. 10th, p. 106, it is stated that a doctor is "prohibited by statute from making any charge in respect of a certificate of the cause of death." This is hardly so. He is entitled to make a charge to the relatives or executors. The point is that he cannot be paid *out of public funds*. The doctor can be fined 40*s*. or get seven years if he *refuses* to issue a certificate of the cause, always provided that he can refuse if he has reasonable grounds for refusing. If there be any doubt about a fee, then the doctor can inspect the dead body and charge both fees for visit and inspection.

Those wishing to obtain very full information should obtain the report of the Select Committee, House of Commons, on Death Certification of August and September, 1893. I gave a large amount of information before this Committee. May I suggest that each medical society shall pass a resolution instructing all its members to inspect the body before certifying? It is full time we adopted a uniform system—that is, if doctors can adopt any system of uniformity.

I am, Sir, yours faithfully,
Liverpool, Jan. 19th, 1920. R. R. RENTOUL.

⁂ Dr. Rentoul's suggestion is not new, and the advantages and objections are well known.—ED. L.

DISCONTENT IN THE INDIAN MEDICAL SERVICE.

To the Editor of THE LANCET.

SIR,—In your issue of Nov. 29th, 1919, the Secretary for War is reported to have replied to Sir Watson Cheyne in the House of Commons, concerning grievances of temporary R.A.M.C. officers, that the pay of these officers has been raised to Rs.750 to Rs.800 per mensem. As this may easily create an impression that medical officers in India are rolling in wealth, may I point out that Special Reservists are only in receipt of Rs.475 per mensem, plus Rs.69–12 for war bonus, a difference of approximately £20 a month.

I am, Sir, yours faithfully,
Jan. 1st, 1920. SPECIAL RESERVIST.

THE JUSTIFIABILITY OF THERAPEUTIC LYING.

To the Editor of THE LANCET.

SIR,—The controversy on the justifiability of therapeutic lying raises a subject of the utmost importance. It involves the question whether mere ritual or ceremony is ever justifiable, when it is intended to deceive or to impress. Whether, also, such cures are good or justified when no effort is made by the patient and nothing is given to dethrone his egoism. Whether humbug is ever justified. Until the public knows the difference between functional and organic disease, and how that the one is frequently superimposed upon the other, such "cures" tend to obscure knowledge and to impede the progress of truth, and, moreover, charlatanism and quackery will flourish. The friends and relatives of Dr. Hildred Carlill's patient are probably deceived. As it happens the patient fell into good hands, but he might as easily have fallen into hands less scrupulous and less honourable, with a similar result and a similar obscuring of knowledge.

One pauses, however, when one reads that "He spat on the ground, and made clay of the spittle and anointed his eyes with the clay and said unto him, Go, wash in the pool of Siloam. He went away therefore and washed and came seeing." But in two other accounts, and those earlier and probably more strictly literal, no ceremony is recorded and the blind man was spoken to thus: "Go thy way, thy faith hath made thee whole; and straightway he received his sight." It may be that the cure of functional disease is more the work of the priest than of the physician, but the priest must be one moved by no unworthy arts of gain, and unnecessary ritual is perhaps better avoided. We know that cures are effected by suggestion of many kinds;—"suggestion" in inverted commas, the eloquence of a quack, vibrations, electric sparks, the reputation of a herbalist, Christian Science, a bottle of medicine three times a day, and relics.

It is pathetic with what earnestness a pilgrim to Lourdes will endeavour to persuade one that the cures effected there are genuine. We *know* that they are genuine, but suggestion will not restore a lost limb, or a nerve tract that has been destroyed, nor cause regeneration of renal epithelium, nor give vitamines to protoplasm; and though the first of these is obvious to the layman the others are not, and if he is bewildered and deceived by our profession how will the truth about disease ever get disseminated? If Dr. Carlill explained the whole thing to the relatives perhaps comparatively little harm was done; but what would be the effect if the patient read the article and the letters on his case? There is no alliance between his moral strength and his recovery. What, in any case, will his future be? Will other devils worse than the first come to occupy the empty chamber? If so, it may well be that a millstone would be preferable to the bone disc about his neck. Elizabeth Barrett was left with no empty chamber. Robert Browning more than filled it; and the blind man had his faith. While we might seek to emulate the atmosphere of the old Æsculapian temples for its curative effect, we would not descend to the crude charlatanism of their ceremonies nor re-introduce the "cure by sympathy" as advocated by Sir Kenelm Digby.

Possibly if the whole world knew what is meant by functional disease and could recognise it, a great deal of, if not all, truly functional disease would tend automatically to disappear.

I am, Sir, yours faithfully,

London, Jan. 19th, 1920. F. READY.

THE LATE SIR VICTOR HORSLEY.

To the Editor of THE LANCET.

SIR,—The memory of this great surgeon-investigator deserves plenty of contemporary comment, as we are reminded by Dr. Giovanni's book, to which you alluded last week, as well as by your review of Mr. Stephen Paget's biography of Horsley. For instance, it will be important for various future students to know that he, the typical Radical, was the complete opposite of his graceful biographer. Would it indeed have improved Horsley's example, as Mr. Paget thinks, for him to have been a public school man? Might it not have hampered his fine initiative during the all too few youthful years of brisk brain? A sometime fellow resident of his has described him to me sitting in the house surgeons' room holding a chloroformed handkerchief to his face and counting his pulse; gradually sinking back in the chair unconscious; coming to again and resuming the record. I for one cannot fancy the public school boy bringing himself to this; the public school boy would have a different notion of public behaviour. However, that common and well-seeming product might find a trifle or two to put in the opposite scale. I remember hearing Horsley speak at a big women's suffragist meeting in Hyde Park. The particular wagon he was on carried the "University platform," and at this, the intellectual hub of the concourse, the weight of advocacy seemed to be sustained by men. However, when it wanted only a few minutes to the ringing of the bell and putting of the resolution, the chairwoman asked him in a superficially careless tone, "Shall I go on a bit now?" A more conventional man, and the modern type of doctor, would have let her; Horsley didn't. The public school might have saved other people's feelings a little, but then even Horsley's stride was not too big to be clogged somewhat by a clerical-authoritarian régime in his impressionable years. For, though wonderfully productive on his plane, he was not the sovereign investigator. He could not "fancy the fabric," could not make big generalisations. His ascent to knowledge was always by way of the staircase, as the French say, although it must be admitted he went up it three steps at a time. He had always more of an eye to the practical, more of the faculty of application of principles, than has your true diviner. In his work, in short, he was limited to Baconian induction, which some eminent contemporaries are always wrongly indicating as the only way of medical investigation.

Where he indeed *may* have lost was by not taking out a university arts course, instead of going straight to hospital, 45 years ago. Even a pass B.A. would have removed his sciolism. Now that is a cheeky word to use in connexion with such a man, and I would not be misunderstood. "All these reveries and studies have need of so much time and thought that it is almost certain a man cannot be a successful doctor, or engineer, or Cabinet Minister, and have a culture good enough to escape the mockery of the ragged art student who comes of an evening sometimes to borrow a half sovereign"—says Mr. Yeats. Remember that to studies and reveries enough Horsley joined brilliant action. If he had had more humanism he would have been less cocksure. A sub-alcoholic combatant officer who had served with him in the East told me that Horsley gave out you couldn't get heat-stroke if you didn't drink. "Then," he added, "he got it himself." Alas, that characteristic and lamentable death robbed us of one who might, possibly, have done giant's work in the slow but sure, post-war revival of truth.

I am, Sir, yours faithfully,

Jan. 20th, 1920. CADUCEUS.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following are the results of the Triple Qualification Examination:—

SECOND EXAMINATION.

Gerrit Johannes Lamprecht, Rachel Caplan, Oliver Hugh Dickinson Oliver, Kaja Magdon Ismail, James M'Nie Campbell, Joseph Alfred Henry Sykes, James Maxton M'Innes, Gujar Robert Falcon, Esias Andries Nortje, and James Readdie.

THIRD EXAMINATION.

Pauline Figdor, Gwilym ap Vychan Jones, John Hagard, John Matthew, Duncan Reid Nicol, Arthur Cuthbertson, Cedric Holmes, and Sayed Ghaleb.

FINAL EXAMINATION.

Lizzie Robertson Clark, Joseph Campbell, James Charles Meek, Alexander Strang, Walter Frederick Swanton Webb, Frederick William Thompson, Evert Frederick Birkenstock, Janet Adeline Agnes Sang, Thomas Blaney, Robert Carl Fechter, and Thomas Wyper Stewart.

Mr. J. B. Joel and Mr. S. B. Joel have made the magnificent gift of £20,000 for the endowment of a chair of Physics in the University of London. The chair will be tenable at the Middlesex Hospital Medical School.

THE IMPERIAL WAR MUSEUM.—The exhibition of the nation's war paintings, which was announced to close this week, will be open until Feb. 7th, owing to the sustained public interest in the pictures. (See THE LANCET, Jan. 24th, p. 215.)

Monsieur Michailo Gavrilovitch, the new Serbian Minister, has become president of the Serbian Red Cross Society in Great Britain, in succession to Yovan Yovanovitch, who has returned to Serbia.

ST. MARY'S HOSPITAL FOR WOMEN AND CHILDREN, PLAISTOW.—Lady Helen Seymour is organising a grand bazaar to be held at Claridge's Hotel on Thursday, April 15th, in aid of the matron's special fund for building a new home for the nurses. It is earnestly hoped that it will be a great success. An urgent appeal is issued to every doctor who has at some time been attached to the hospital to send a trifle for the hospital stall. However small, it will be gratefully acknowledged by the matron.

University College Hospital being somewhat small for the large schemes in contemplation there, the committee have recently acquired a site in the immediate vicinity of the hospital on which to build a nursing home, with a view to liberating the part of the hospital at present occupied by nurses for the purpose of providing additional beds for patients.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—The medical and surgical units at University College Hospital Medical School have now been instituted and are in full working order. The director of the medical unit is Dr. T. R. Elliott, C.B.E., D.S.O., F.R.S., physician to the hospital. Dr. J. W. McNee, D.S.O., recently assistant to the Regius professor of medicine and to the professor of pathology at Glasgow, has been appointed first assistant and deputy to the director. Dr. F. M. R. Walshe has been appointed second assistant to the director to control neurological teaching and research, and also to take charge of the department at University College Hospital of electro-therapeutics and massage. The director of the surgical unit is Mr. C. C. Choyce, C.M.G., C.B.E., and he has as his first assistant Mr. E. K. Martin, and as his second assistant Mr. F. J. F. Barrington. The directors of the units are responsible for the general arrangement of systematic teaching on the principles of medicine and surgery in both hospital and school. The instruction of junior students in physical signs and elementary laboratory methods and the systematic demonstrations and lectures for senior students are to be organised by them, although the teaching in these courses is in certain cases given by other members of the staff. Every student is to take duty during his first year for two months' clerking and two months' dressing with the medical and surgical units respectively. These terms of clerking and dressing are intended to follow as far as possible the four months' term of duty with other members of the staff. Thus every student will in due course pass through one or other unit. During his course of two months' duty under the director of the medical unit the student will be attached for clinical clerking to some of the special departments, such as the cardiographic department under Dr. Thomas Lewis, F.R.S. Arrangements have been made at the medical school by which the directors of the units and their assistants have been furnished with ample accommodation and facilities for research work in the Graham Laboratories of Pathology.

Under the auspices of the Fellowship of Medicine lectures and practical work in physics for the Cambridge diploma in radiology will be given at University College Hospital, London, commencing Tuesday, Feb. 3rd, at 5.30 P.M. Applications should be addressed to the hospital.

No. 20 General Hospital, B.E.F.—A dinner of the officers attached to this hospital during the campaign in France, at which Major-General Guise Moores, C.B., will preside, will be held in London on March 13th. Any who are desirous of being present are asked to communicate with Mr. H. Drinkwater, at 7, Cavendish-place, London, W.

Scottish Poor-law Medical Officers' Association.—The annual meeting of the association is being held to-day (Friday) at the St. Enoch Station Hotel, Glasgow. The report for the year 1919 states that the superannuation for all employees of local authorities has been under consideration. Dr. W. Bryce and Dr. W. L. Muir have been nominated to serve on the consultative council to advise the Scottish Board of Health.

The Federation of Medical and Allied Societies.—At the last meeting of the executive of the federation it was decided to hold a dinner at the Café Royal, Regent-street, London, at 7.30 P.M., on Wednesday, Feb. 25th, when the guest of honour will be Sir Bertrand Dawson, whose elevation to the peerage has recently been announced. Tickets are 35*s*. inclusive of wines, and some who intend to be present have intimated their intention to bring guests. Saturday, Feb. 14th, is the last day on which it will be possible to receive applications for tickets, which should be made to Dr. N. Howard Mummery, general secretary, at 5, Vere-street, Cavendish-square, London, W. 1.

The British Dental Association.—The new headquarters of the British Dental Association were opened by Dr. Addison, the Minister of Health, at 23, Russell-square, London, W.C., on Jan. 23rd. Sir George Newman, Chief Medical Officer of the Ministry of Health, was present to represent the University of London, and a distinguished attendance included Sir George Makins, President of the Royal College of Surgeons of England; Sir Humphry Rolleston, President of the Royal Society of Medicine; Surgeon Rear-Admiral Sir R. Hill, Director-General of the Medical Department of the Royal Navy; and Major-General Sir G. Stanistreet, Deputy Director, Army Medical Service. Among those who were unavoidably absent and who sent letters of regret and support were Sir Donald MacAlister, Sir Clifford Allbutt, and Sir John Goodwin.

Mr. Montagu F. Hopson, President of the Association, who presided, said that the accommodation in Hanover-square, having proved too small for the requirements of the Association, the new premises had been adapted at a present cost of £4000, the charge being made out of funds held in reserve for the purpose. A generous donation had been received from the mother branch and other donations from individual members. He hoped that the new home would prove worthy of the work which the Association would be called upon to do in the near future. The Association was founded just after the passing of the Dentist Act of 1878, and had now a membership of 3000—that was to say, three-fifths of those qualified to practise dental surgery. The Association might therefore be considered as truly representative of British dentistry. Dr. Addison, in formally declaring the new headquarters open, said that dentistry had not yet come into its kingdom, and he was glad to see that the Association had been able to find the means necessary to equip itself with better headquarters. He hoped, too, that there would be only one association, for it was the plague of some professions that they had too many. The report of the Dentist Act Committee had indicated what it was necessary to do as a minimum in the interests of public health, but as developments went on it would be found that there would be an insufficient supply of skilled men. The dentistry training was perhaps more expensive than the medical training. It ought to come within the reach of a larger number of people, and he was glad to see that a reduction in the period of training had been recommended. Medical research had shown that the health of the nation's children was being undermined in consequence of defective teeth. In the proposals that would be put before the country by the Government in due course it was essential that everyone should understand that the organisation and trained personnel for an adequate service would take many years to provide. In any proper organisation, too, there should be community of service, and the time was rapidly coming to an end when in respect to health services medical men, dentists, nurses, midwives, and others would be taken separately. The aim should be a coördinated service working in common centres. Mr. Norman G. Bennett proposed a vote of thanks to Dr. Addison, which was seconded by Major W. Guy, of Edinburgh, and carried with acclamation. Mr. J. A. Woods proposed a vote of thanks to the distinguished visitors, which was replied to by Sir George Makins, and the proceedings terminated.

Central Midwives Board.—A meeting of the Central Midwives Board was held at Queen Anne's Gate Buildings, Westminster, on Jan. 22nd, with Sir Francis H. Champneys in the chair.—A letter was considered from the secretary of the County Councils Association asking the opinion of the Board as to the practicability of restricting the liability of local supervising authorities under Section 14 of the Midwives Act, 1918, by the imposition of a time limit or otherwise. The Board directed that the secretary of the County Councils Association be informed that the Board does not see its way to advise what limits should be placed on the liability of local supervising authorities under Section 14 of the Midwives Act, 1918, but thinks that each case must be considered on its merits as to when the emergency ceases.

A special meeting was held on the same date, when two midwives were struck off the roll, the following charges amongst others having been brought forward:—

> Being in attendance at a confinement and the patient suffering from serious rupture of the perineum and offensive discharge, the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rules E. 20 and 21 (3); she neglected to take and record the pulse and temperature of the patient at each visit, as required by Rule E. 14, and the child having died before the attendance of a registered medical practitioner, the midwife neglected to notify the local supervising authority thereof, as prescribed by Rule E. 22 (1) (b). A child suffering from inflammation of and discharge from the eyes and continuing so to suffer, the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as provided by Rule E. 21 (5); medical aid having been sought for the child, she neglected to notify the local supervising authority thereof, as required by Rule E. 22 (1) (a).

Hospital Conditions in Leeds.—The stocktaking in charitable institutions, and especially in hospitals, has this year been followed by a feeling of dismay. The plight of Leeds is really that of all provincial hospitals, as is revealed by correspondents in The Lancet from Bristol, Birmingham, and other centres. Leeds suffers chiefly from a lack of funds, the deficit on each year's working amounting to about £25,820, whilst the bank overdraft reaches £38,591. This year Mr. Joseph Watson prevented disaster with a magnificent gift of £50,000, but even this is but a temporary help. Further schemes for the raising of the yearly income are afoot. The number of beds at the disposal of the infirmary authorities is 594, but some are occupied by special military cases, and 64 beds are kept for pensioners; this causes a waiting list of several hundred civilian patients, but there are signs that this state of affairs will be remedied in the near future. The aggregation of all kinds of cases at the General Infirmary at Leeds is ideal for students and teachers alike. In provincial cities, where more than one institution exists, much may be said for coöperation and central control. Buying on a large scale can command an easier market; efficient administration can be afforded; staff personnel kept at a higher level; whilst funds and effort in collecting them are not frittered away, thus giving the subscribing public a better assurance that their money is being spent to the highest advantage. In Leeds, where the workpeople subscribe to a common hospital fund, much trouble and annoyance associated with the distribution of the moneys thereof would be done away with by centralisation of control.

Norfolk and Norwich Hospital.—The quarterly meeting of the governors of the Norfolk and Norwich Hospital was held on Jan. 10th. The board of management reported that during the past quarter 10 military cases, 172 discharged soldiers, and 666 civilians, a total of 848, had been admitted to the hospital, the number in the corresponding quarter of the previous year having been 750. The average daily number of in-patients was 277, against 304 in the corresponding quarter of 1918; 587 operations had been performed, against 437; 497 new cases were treated in the out-patient department, against 393; and 1771 accidents and casualties had been treated, as against 1231 in 1918. It was also pointed out that whereas in 1913 the total number of in-patients was 2667 and the average number of patients resident daily was 180, in 1918 the total of in-patients was 4242 and the daily average 328, yet the daily cost per in-patient had increased from £4 13*s*. to £8 13*s*. 6*d*. In 1913 the annual subscriptions amounted to £3485, and had only increased in 1918 to £4010. On the other hand, the expenditure had increased from £13,650 to £36,653. These figures were sufficient to show the good work done by the hospital and the urgent need of a great increase in the annual subscriptions. The special appeal fund for the establishment of an orthopædic department and for other extensions had been augmented during the quarter by £1000, and now amounted to over £21,000. There were two interesting contributions made during the quarter, the first being a donation of £100 from the King and the second was a sum of £229, the result of the takings on Dec. 12th last at all the cinema theatres in Norwich, the proprietors of which had generously presented the receipts for that day to the special fund. The board is appealing for a further sum of from £16,000 to £20,000.

Appointments.

Notes, Short Comments, and Answers to Correspondents.

AMUSEMENTS AND THEIR EFFECTS.

BY HERBERT CARSON, F.R.C.S. ENG.

IN the course of a lecture delivered at the Institute of Hygiene on Jan. 21st, Mr. Herbert Carson said that amusement was necessary for civilised people as it had a definite effect on health and the recuperative powers. There was a definite ratio, too, between efficiency and fatigue, so that a shorter working day might result in greater output, better work, and fewer accidents. But the consequent increase of leisure made it necessary that the workers should be taught how to spend it, and the true interests of the community demanded that the workers should be instructed in the value of leisure. Marking the difference between urban and rural populations, he said that the inhabitants of rural districts did not favour field sports, probably because their feet were too often on the turf, and the absence of amusements resulted in desultory discussions and ill-natured gossip at the village inn. There was great need for the organisation of village centres providing clubs, reading rooms, lending libraries, discussion circles, and social games—free from the domination of the Church. In the towns a large army of people was employed in promoting amusements for others and enormous sums were spent. The entertainment tax brought in last year over £7,000,000, which meant that, in taxed amusements alone, £50,000,000 was spent, or about one-fortieth of the whole national income. Professional sport was now at the height of its vogue, and the first round of the Football Association Cup had drawn £36,000 from 526,000 spectators at [illegible] matches—or sufficient money to maintain a hospital of 200 beds for a whole year and confer lasting benefit on 3000 in-patients and 50,000 out-patients. Active amusements provided the ideal way of spending leisure. Economic changes due to the war had caused a decline in the outdoor sports of the wealthy, such as polo and hunting, and even golf was becoming an expensive game. Cricket and football remained as the recreations of the many; and, now that the danger of critical shortage of food was past, he considered that the acreage in open spaces which had been diverted to allotments should be returned to its original use.

Strenuous Week-ends.

As a medical man, he thought it necessary to issue a gentle warning against the strenuous week-end. Many hard-driven business men rushed off at Saturday midday for an orgy of exercise. They played golf or tennis with great vigour throughout the week-end, and "slept like a top." But it was really the sleep of bodily exhaustion which, during what should have been a period of rest, they had added to the mental strain of the week's business; and with the shady side of 40 this would tell. The craze for dancing might appear to be going too far, and the atmosphere of the ballroom was certainly not perfect hygienically. But he considered that it was productive of much useful development, and that any tendency to abuse would adjust itself. Night clubs and bridge clubs were becoming a serious scandal, and were the best proof that we do not know what to do with our leisure.

Educational Possibilities of the Cinema.

Concerning the cinema, Mr. Carson said that it made a great appeal by its cheapness, and, although much trashy stuff was presented, it succeeded in bringing amusement to millions who had not previously been catered for. Cinema halls were not hygienically commendable, as they excluded light and air and did not permit free ventilation, and there was danger of infection. The cinema had great educational possibilities, as it was easier to teach through the eye than through the ear, but he did not consider that mixed educational and entertainment programmes would prove popular. The theatres had had a great boom, and it did not seem to matter much what quality of entertainment was provided. Revue followed revue with similar music and the same jokes; but better things came from time to time, when a Moscovitch interpreted Shylock in a way that would have delighted Shakespeare, and the character of Abraham Lincoln, in Mr. Drinkwater's play, was delineated in a lovable manner. But audiences were curiously uncritical, and solaced themselves with chocolates as an antidote to depressing entertainments.

Recreation for Women and Children.

The population at large, and especially the children, were being deprived of opportunities for recreation by allotments which probably added little to food supplies and provided exercise for only a very few. The question of amusements for children was really the most important aspect of the whole subject, and the value of play centres for elementary school children and the effect of organised games at secondary schools are the outstanding points of interest. These may have the most important bearing on the health of future generations. A great advance was taking place in active recreation for women. The games mistress and director of physical education was now an important member of the staff at all schools, and the girl of to-day, with her well-developed body and fearless outlook on life, compared most favourably with her Victorian predecessors. The social welfare movement among working women instilled in them the general principles of hygiene, improved their health, and made their work a pleasure to them. Little had yet been done for the working man's wife. She had increased leisure now that children could be fed at the schools and entertained at the play centres, but little recreation had been provided for her.

The Public House as the Poor Man's Club.

It was still the public-house that gave the poor man the chance of meeting his fellows. Although unsavoury, it was the poor man's club, and was often cleaner, warmer, and more jolly than his own home. The existing public-house was a disgrace to our civilisation, and would probably not be allowed to continue in any country but this. The many efforts made to improve it were strongly opposed by temperance advocates, who feared that a decent type of public-house would attract more people, and by the trade, which feared that customers would stay too long with too little outlay of money.

THE PURSUIT OF THE LOUSE.

UNDER the auspices of the London County Council a lecture to teachers and others was given on Jan. 26th at the South Western Polytechnic, Chelsea, by Mr. A. Bacot, entomologist to the Lister Institute of Preventive Medicine, on Lice-borne Diseases and their Treatment. Mr. Bacot, whose lecture was illustrated with lantern pictures and supplemented by a microscopic demonstration, described the three kinds of lice which breed upon man. Two of them, the head and the body louse, were so closely related that it was doubtful if they could rank as species, while the third, the crab louse, was not so widely spread, as its conditions of existence were more limited. The well-recognised association between dirt and lice was due to the fact that the conditions which led to neglect of the body and the clothes were favourable to the spread of the insects, but dirt in itself was not a necessary condition of their propagation. Poverty led to lousiness; not only material poverty, but also that of intellect and physique. Old and infirm people could not always keep their body and clothes free from the pests, and in the past the mental attitude which associated dirt and holiness encouraged lousiness. In the case of the modern tramp it was often the mental outlook that led to his manner of life. The conditions which prevailed in the trenches were due to the fact that the results of crowding men together were not recognised early enough. In civil life the frequent changing of clothes brought about an environment in which, although the louse might live, it could not breed. The louse hatched out of the egg in a state very similar to that of its parent, and, after moulting three times, became an adult insect in about 12 days. The temperature necessary for successful breeding was between 75° and 90° F. The mature life of the louse infesting body and head might extend to 35 or 45 days, the number of eggs laid during that period being about 300. The pubic louse, on the other hand, laid only about 50. The body louse and her daughters together might lay about 4000 eggs during the mother's lifetime, and after her death the daughters would lay up to 12,000 eggs during the remainder of their lives. The louse depended for its existence on the blood of its host, and removed from the body of the host the insects did not live long. The effects of bites apart from disease differed over wide limits among different individuals, one man showing practically no effects and another a marked effusion of blood over the surface of a whole limb, or in other cases the formation of watery pustules.

Lice-borne Disease.

Of the three fevers conveyed by lice (typhus, trench fever, and relapsing fever), typhus was the most serious, and had always been associated with war and famine in Europe. Lice did not transmit a disease unless they had first bitten a patient suffering therefrom, but in the case of typhus fever it was suspected that the female might pass on the disease to her eggs. Referring to the ravages of typhus in Europe, Mr. Bacot said that what this country must really depend upon as a safeguard was such a high standard of health and cleanliness that people did not become lousy. If such conditions were maintained we should certainly get no general epidemic, even though one should occur as near as France. The danger arose when people were so poor that they were afraid of having their clothes washed for fear of injuring them. Discussing the methods of destroying lice, the lecturer said that in the case of clothes dry heat was best, and it could be done in an ordinary oven with a temperature of 52° C. or 124° F. Moist heat was also effective, but it must be applied with judgment otherwise the results were not satisfactory. For application to the body various oils could be used, such as sassafras mixed with paraffin or kerosine, and he had found light wood oil[1] most effective. The essential thing was to have penetrative power combined with prevention of evaporation. This was attained, for example, by the admixture of vaseline and kerosine. Objectionable smells from the oils could be disguised with camphor. Nothing was known which would dissolve the cement which fixed the eggs to the hair, but it could be so modified with acids as to loosen it and make it possible for the eggs to be drawn off with a comb.

THE ÆTIOLOGY OF CARCINOMA OF THE BREAST.

A CORRESPONDENT has recently suggested as a factor in the ætiology of carcinoma of the breast the perverted action of ovarian hormones. He draws attention to the close physiological connexion between the mammæ and the genitalia, and suggests that at the climacteric, which corresponds to the average age-incidence of carcinoma of the breast, the genital hormones, being no longer required to stimulate physiological development of the breast, undergo a degeneration and give rise to pathological development. It is a good working rule that the onus of the proof of any theory lies upon the author thereof; it is one thing to enunciate a hypothesis, but quite a different thing to bring it into line with such stubborn things as facts.

A few years ago this very theory was brought forward as the basis of a method of treatment of inoperable cancer of the breast. As has invariably happened in the history of malignant disease, some remarkable cures resulted from the new treatment, but favourable results became fewer with extended experience, and oöphorectomy is no longer performed for carcinoma of the breast. There is, in point of fact, no theoretical support for this form of treatment. The age-incidence of carcinoma of the breast is rather later than the climacteric, but, on the other hand, it is much the same as the age-incidence of carcinoma in other organs on which, so far as we know, ovarian hormones have no action whatever. Again, the fairly high incidence of the disease in women before the age of 40 and its occasional occurrence in the male are both inexplicable by this theory. There is plenty of evidence to show that reactive inflammatory lesions are the most constant precursors of the malignant change in the breast glands, but there is no anatomical basis for the belief that these changes are connected in any way with morbid processes in other organs.

PUBLIC HEALTH AT COLOMBO, 1918.

THE population of Colombo at the middle of 1918 was estimated at 264,746, of whom 118,767 were native Sinhalese, 64,133 Tamils (Southern Indians), 46.643 Moors (of Arab descent), 17,361 Burghers (of Dutch or Portuguese origin), and 3700 Europeans, the remaining 14,142 consisting of Malays and others. The general birth-rate was 22·4 per 1000, and for Sinhalese it was 28·1; amongst Malays it was 41·2, and amongst Tamils only 13·2 per 1000. The general crude death-rate was 28·0, compared with 29·0 for the decennium, 1908–17; as corrected for hospital deaths of non-residents and for age and sex constitution, the ratio was 29·4 per 1000; this is extremely satisfactory, considering the severe invasion of influenza. Amongst Malays the ratio was 37·4, Sinhalese 32·1, Tamils 23·2, Moors 24·7, and in Europeans only 13·0 per 1000; if corrected for deaths in institutions this last ratio is reduced to 9·5 per 1000. The chief cause of death was pulmonary disease in some form or other; the total mortality from this group of affections amounted to 2479 deaths (9·40 per 1000), pneumonia (6·12) and phthisis (2·53) being the chief causes, due to influenza. Of enteric fever there were 430 cases (1·62 per 1000), with 181 deaths; this gives a case-mortality of 42·1 per cent. (and in regard to Moors 65·7 per cent.), thus indicating that there must have been many cases not notified. There were only 13 cases among Europeans, with 3 deaths; all of these cases (except 3) contracted infection away from Colombo. The incidence of plague (0·27 cases per 1000) was lower than in any year since the commencement of the pandemic; there were only 70 cases (69 fatal),

---

[1] Light wood oil is a by-product obtained in the making of acetone by the destructive distillation of wood. We understand that at the present it is not in the commercial market, but probably the Ministry of Munitions would be able to supply institutions and other public bodies who required it. The price, probably a few pence per pound, would compare very favourably with sassafras oil.

35 being amongst Tamils, and none occurring in the European population; the incidence was chiefly in St. Paul's Ward (25 cases), and the rat infection, though on the whole slight (0·29 per cent. infected out of 21,000 examined), was considerable in the Fort Ward, where it was promptly suppressed by the use of Clayton fumigators and pesterine. Influenza became epidemic in Colombo in June and July, especially in the neighbourhood of the harbour, but was of mild type (6 cases fatal) and rapidly disappeared. During the third week in September a fresh outbreak occurred, complicated with a very virulent and rapidly fatal form of pneumonia; the actual number of cases cannot be stated, but in October and November 9200 cases (including 961 cases of pneumonia) were treated by the municipal staff alone. There were 275 deaths actually recorded throughout the year, but Dr. William Marshall Philip, the medical officer of health, who presents this very interesting report, considers that this figure does not by any means represent the real mortality due to the disease. The total deaths from pulmonary affections registered in 1918 were 21 per cent. in excess of the average for 1903–1918 (7·77 per 1000), and for pneumonia alone 80 per cent. above the mean (3·40 per 1000). This is graphically illustrated by diagrams. The report is accompanied by an excellent map, which adds considerably to its value.

MALARIA IN THE FEDERATED MALAY STATES.

IN 1911 a Board was constituted for the purpose of advising the Government of the Federated Malay States in the carrying out of a general campaign against malaria. Its chief aims were the collection of information as to the causes, incidence, and effects of the disease, the education of the people in this connexion, and the extermination of anopheles in all thickly populated centres, and (where practicable) in rural areas. The Board has for its president the Chief Secretary to Government, Sir Edward Brockman, K.C.M.G., and the principal medical officer, Dr. C. L. Sansom, C.M.G., for its vice-president. The executive engineer operates under the authority of the Board; the medical entomologist reports to the Board, but is independent as regards methods of investigation and expression of opinion. Dr. C. Strickland was medical entomologist from 1912 to 1917, in which latter year he presented his final report on the biology of the anopheles mosquitoes of the Malay peninsula. Dr. Strickland was succeeded by Dr. H. P. Hacker in February, 1917. The report states that:—

> The experimental work done on the relation between mosquitoes and malaria is mainly of value as indicating the lines on which further investigations should proceed. Experiments made in infecting various species of mosquitoes and in transmitting malaria from man to man, and observations on the prevalence of various species, their breeding places, and other features, have clearly pointed to the existence of factors which are not yet understood, and the importance of further and adequate researches to elucidate such factors. ...... It would appear that severe malaria has occurred at times when but few anophelines or little anopheline breeding were evident, and that little malaria has been apparent when anophelines were numerous. ...... The further study of species is therefore essential.

Mistakes appear to have been made in the drainage operations undertaken some years back, but since the end of 1912 "it could be safely claimed that malarial infection was rare within the district protected by drainage." Since then the works have been considerably extended, though war conditions have caused delay. Oiling of breeding-places has also been practised. Dr. Strickland's observations led him to the belief that in most hill land jungle no malaria-carrying anopheles exist, and that the preservation of such jungle in hill land ravines and swamps is an important anti-malarial measure; he did not apply the argument to coastal jungle other than mangrove forest, and obviously great watchfulness as to results would be necessary. Kuala Lumpur, the seat of government for the Federated States, with a population of 47,000, has now been provided with efficient land drainage for an area of 4500 acres, and at an expense of 231,679 dollars for construction, with an annual maintenance charge of 10,000 dollars; drainage works are in hand for a considerable additional area in the low ground to the north and east, and some high ground to the west is receiving attention from private authorities. The report concludes with the statement that "malaria is beyond dispute the great natural obstacle to the economical and humane development of the Malay States, and equally concerns all classes of the community." That it will yield to a suitable campaign admits of no doubt, and the progress already made is a sufficient guarantee.

METRIC PRESCRIBING.

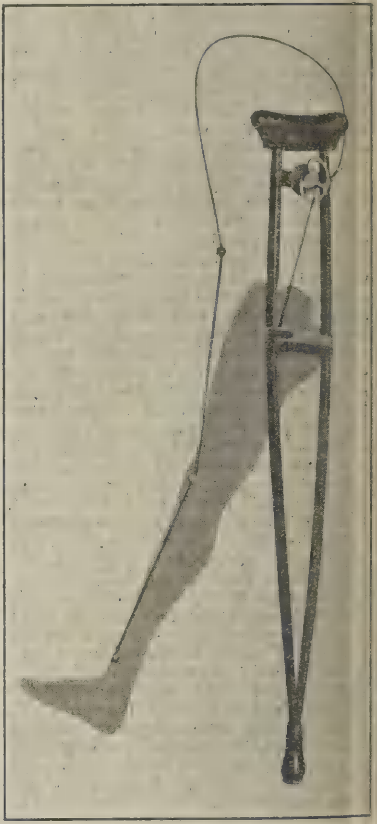
To the Editor of THE LANCET.

SIR,—With reference to Dr. Wright Hardwicke's interesting letter in your issue of Jan. 17th, saying that it is the continental custom of placing the denomination instead of the decimal point between the integer and fraction (for instance, 8 g. 5 instead of 8·5 g.), in this method there would seem to be contravention of two of the rules laid down by an International Committee (that is, according to the Reichs-Medizinal Kalender, by Dr. Paul Börner, published in 1914). He there states: "Die offiziellen Abkürzungen für die Masseinheiten sind gelegentlich der letzten Sitzung des internationalen Komitees für Masse und Gewichte festgesetzt worden," and adds, as rule No. 1, "Den Buchstaben werden Schlusspunkte nicht beigefügt" (the letters will not be followed by any fullstop). Thus I understand 5 g not 5 g. is meant. Rule No. 2, "Die Buchstaben werden an das Ende der vollständigen Zahlenausdrücke—nicht über das Dezimalkomma derselben—gesetzt, also 5,37 m—nicht 5 m 37 und nicht 5 m 37 cm." (The letters will be placed at the end of the complete figure expression, not against the decimal comma, thus 5,37 m—not 5 m 37 and not 5 m 37 cm.)—I am, Sir, yours faithfully,

Jan. 18th, 1920. W.

A CRUTCH WHICH ENABLES A PARAPLEGIC TO WALK.

AT the meeting of the Académie de Médecine of Paris on Dec. 2nd last M. Gabriel Bidou showed a very ingenious mechanism which can be applied to any crutch; it works by utilising pressure of the hand on a lever to elevate and flex the lower limbs on the pelvis. It is particularly useful in all forms of paraplegia, but may also be used in cases of paresis or temporary weakness of the lower limbs. It consists of a pulley, on which runs a cord, and of an "eccentric," or cam, as engineers term it, fixed on the same axis as the pulley. Smoothness of movement is ensured by ball-bearings. The whole is fixed to a cross-bar, which can be attached to the upper part of the crutch by two screws. To the handle of the crutch there is also fixed, by two screws, a steel cap bearing a lever which is controlled by the hand. A leather thong attached to the uprights of the crutch, into which the patient passes his arm, as if he were carrying a buckler, allows him to use the crutch while preserving freedom of the hand. A cord connects the lever with the pulley, and another cord connects the cam with the patient's leg, passing through a protective sheath, like that of the brake of a bicycle, beneath the clothes. The apparatus is used as follows. The paraplegic supports himself on four points — the two lower limbs and the two crutches. His centre of gravity then lies over the middle of the quadrilateral so formed. He walks in the following manner. Carrying slightly the weight of his body to one side he transforms the basis of support into a triangle formed by the two crutches and one lower limb. Thus by the lateral inclination of the body he sets free the other lower limb. At this moment he leans on the lever and raises the limb. When the limb has been brought forward and applied to the ground the paraplegic will bear on it, and his triangle of support, instead of being right, for example, will become left. He then goes through the same process with the other limb, and so progresses. The cord which drags the lower limb may be attached to the front of the boot by a ring, either on the right side or the left, according as it has to pull against opposition of adductors or abductors. This simple apparatus ought to prove most useful.



Some Remarks
ON
"BONE-SETTING":
THE PRACTICE AND RESULTS OF FORCED MOVEMENT.

By JAMES B. MENNELL, M.D. CANTAB.,
PHYSICIAN IN CHARGE MASSAGE DEPARTMENT, SPECIAL MILITARY SURGICAL HOSPITAL, SHEPHERD'S BUSH, W.; MEDICAL OFFICER, PHYSICO-THERAPEUTIC DEPARTMENT, ST. THOMAS'S HOSPITAL.

THE whole subject of the treatment of the after-effects of injury is interwoven with that of the administration of forced movement, and this in turn is intimately connected with the art of what is commonly known as "bone-setting." The principles which underly the administration of forced movement in the massage-room are very similar to those that should control forced movement under an anæsthetic. I am constantly asked to expound the principles of "bone-setting," to explain as far as I may why the quack "bone-setter" is able to flourish so exceedingly, and to compare the results of "bone-setting" with those of orthodox practice. The first reflection is that the material on which the "bone-setter" thrives should never exist. This does not mean that the formation of adhesions can always be wholly prevented, but it should be, and may be, very greatly eliminated; and, whenever this is impossible, the adhesions should be broken down at the earliest possible moment. Speaking generally, it may be said that the "bone-setter" flourishes, not because people suffer injury, but on account of the treatment they receive. The doctrine of fixation, rest, and splintage is his great ally; his enemy is the treatment of recent injury by mobilisation. Until the time has come when the old teaching of absolute and prolonged rest after injury shall have been supplanted by Lucas-Championnière's doctrine of the scientific combination of rest with mobilisation, the type of disability which fills the "bone-setter's" rooms will never decrease.

But, do what we may, no amount of skill in treatment will always prevent the formation of adhesions after injury, especially in the presence of sepsis; and, if they form, it is essential that we should know how to deal with them, and carry out our treatment as early as possible.

It has fallen to me to encounter many of the failures of the "bone-setter," and from them much may be learnt. I have also had the most valuable and, I believe, uncommon experience of witnessing the results of mobilisation under anæsthesia as practised by a very large number of different surgeons—some, as I believe, too conservative, some too drastic. I have also discussed this subject very widely with surgeons on both sides of the Atlantic, and have been able to form conclusions as the result of these varied experiences. In my own practice I know only too well how often I have withheld my hand when movement under anæsthesia would have saved prolonged treatment, pain, and tedious convalescence. I know, too, why I have been so often tempted thus in the past, and the reason may be summed up in one word—failure. It was only when I realised the cause of failure that I again began to practise manipulation under anæsthesia and formulated the principles which I believe should govern the art. Now this method of treatment is a mainstay on which I frequently rely not only to hasten convalescence, but very often to render possible cure of disability.

CAUSES OF FAILURE.

The cause of my failure in earlier days was dual in origin; first, I did not know what the natural movements of joints were, and second, I tended to do too much. Because a patient is unconscious he cannot feel pain, but this is no excuse for mobilising a joint indiscriminately. During conscious life reflex contraction of the muscles that oppose a movement invariably takes place so as to limit the movement before undue strain is placed upon normal structures. Under anæsthesia this protective reflex is lacking, and so it behoves us, if we would avoid inflicting injury, to exercise even more care when we approach the limit of movement than we should use were the patient conscious.

Then comes a consideration which I believe to be very generally overlooked, but clinical experience has convinced me of its accuracy. This is that adaptive shortening takes place in the body with astounding rapidity, and particularly in the presence of pathological change, even though this change is only reflex wasting of muscle. Each muscle fibre and group of fibres is surrounded by a connective-tissue sheath, and this sheath is endowed with the property of elasticity. Deprived of its function of shortening and lengthening, the sheath seems to lose its capacity very rapidly, and, for the time being, becomes comparatively inextensible. The whole muscle mass, in other words, has undergone adaptive shortening. Restoration of function alone restores the elasticity. If, then, we imagine that the movement, say, of extension of the elbow has been limited by adhesions in or round the joint for some weeks, it follows that the flexors throughout that time have never been fully stretched. The elasticity of the fibrous tissue which goes to the make-up of the anatomical muscular mass has, therefore, never been utilised to the full extent since the day when adhesions which limit extension first began to form. The result is that the elasticity remains unimpaired only through the range of movement allowed by the adhesions. Beyond this range the elasticity is impaired, or, if the lesion is of long standing, may be almost non-existent. When the patient has been anæsthetised and movement has been performed through sufficient amplitude to rupture the adhesions, all further attempt at movement will tend to place undue strain upon the fibrous tissue, which, as we have seen, has suffered impairment of its extensible properties owing to disuse. Forced movement through the full anatomical range may thus inflict severe injury on the fibrous tissue that has lost the elasticity which is essential for the natural performance of the movement.

RULES IN MANIPULATION.

The first golden rule in manipulation under anæsthesia should therefore be that no further attempt at movement is to be made in any direction when once a definite adhesion has been felt to give way. If this rule is ignored injury will inevitably be inflicted on the fibrous tissue which forms a large bulk of the muscles which oppose the movement. Movement in other directions may, however, be continued. Two criticisms then arise. First, full range of movement may not have been restored by one manipulation; and, second, we do not know that, because one adhesion has been broken, there may not be others which still limit movement.

The answer to the first criticism is this. Rupture of a pathological band is practically painless, and the local reaction is mild and transitory when compared with the considerable reaction that follows undue stretching—i.e., spraining—of physiological tissue. There should be, therefore, no interference with function and the voluntary use of the limb after skilled mobilisation, except that due to inelasticity of the fibrous tissue within the muscles, and perhaps a mental incapacity to realise that movement or use, which has hitherto been impossible, is restored. Functional use of the limb will rapidly restore the elasticity either up to the anatomical limit or up to the limit allowed by other adhesions, should these exist. If, on the other hand, we have forced movement to the anatomical limit, and have thereby overstretched the temporarily inelastic fibrous tissue, we have inflicted a more or less severe sprain, since normal movement may be excessive for structures that have undergone adaptive shortening. Thus we inflict a fresh injury which may be no less difficult to cure than that which the patient originally sustained.

The answer to the second criticism is that it is better to break down any second adhesion under a second anæsthetic and inflict no further injury, than to break down both at once and inflict an injury which is a potent predisposing agency to the formation of new adhesions. Essentially is the old adage "More haste, less speed" applicable to forced movement under anæsthesia.

The criterion of success after the manipulation should be that the patient has increased function; loss of function speaks of an error in technique. Unfortunately this is not generally realised, and many surgeons labour under the delusion that, should the necessity of giving a second anæsthetic arise, they made an error in not doing sufficient on the first occasion. The "bone-setter" suffers from no such delusion, and frequently arranges from the outset to perform a series of manipulations when proposing to loosen a joint in which there has been gross limitation of movement for a considerable time. His practice is sound, and we should undoubtedly accept this lesson he teaches. More active harm is done by excessive movement under anæsthesia than passive harm by neglect to use this most valuable remedial agency.

CHOICE OF TIME, ANÆSTHETIC, AND TECHNIQUE.

The question as to when forcible manipulation should be performed is not an easy one to answer. If the injury has been uncomplicated by sepsis, it is probably unwise to proceed until six weeks have elapsed since the receipt of injury. I have fixed this limit for the simple reason that it is by no means certain that the exercise of the voluntary function of the limb will not restore the movement that is lacking till at least this time has elapsed. If sepsis has been present, and if this has obviously played some part in causing the limitation of movement, it is probably unwise to manipulate the part forcibly for several months, three to six, according to the severity of the sepsis. The same applies to cases in which loss of function is due to osteoarthritis and similar causes. I make it a rule also to hold my hand for three months at least in all cases where injury has resulted in the outpouring of an excessive callus formation.

It is not uncommon for attempts to be made to break down adhesions without the aid of an anæsthetic. Provided the limitation of movement is small, and the original injury to the joint in question is probably slight, this is quite justifiable. For instance, it is often a simple matter to rupture adhesions in the inferior radio-ulnar joint after a Colles's fracture without an anæsthetic. On the other hand, an attempt to flex rigid metacarpo-phalangeal joints in similar manner is opposed by the full strength of the long extensors in the forearm, and the movement cannot be performed without severely straining and thus injuring them. It should be a guiding rule, therefore, always to administer an anæsthetic whenever we are liable to encounter severe muscular resistance to our manipulations.

The choice of anæsthetic depends chiefly on the skill of the anæsthetist. Nitrous oxide gas suffices if adequate skill in administration is forthcoming, and if the manipulator knows exactly what to do and how to do it. Very few seconds should suffice for the manipulation of most joints, and a skilled anæsthetist can almost always ensure this much at least of complete relaxation with nitrous oxide gas. For manipulation of the hip or back it is wise to use some other anæsthetic, as more time is required for these manipulations than in most other joints.

The grip employed during manipulation is important. Our aim being to rupture an offending band *and no more*, it is usually wise to use as short a leverage as possible. Then, too, we want to reduce subsequent pain and disability to a minimum, and experience shows that this end is attained better if the adhesions are broken by a single sharp movement than by a slow gradual tearing. Rapidity of movement should be combined as far as is compatible with complete control, which checks the movement the moment the objective—i.e., the rupture of the adhesion—has been attained. On the other hand, nothing could possibly represent a greater error in technique than to give a succession of ineffective tugs on the offending band. Once its resistance is encountered it must be overcome forthwith; once overcome, the movement must instantly cease.

Hutton's statement that force in pulling or pushing is valueless, but that "the twist is the thing," gives the key to manipulations of most joints. The whole art is the knowledge of what precise "twist" to administer to each individual joint.

GENERAL PROCEDURE.

The first thing to ascertain definitely is what movement or movements are limited or give rise to pain, and it is usually wise to compare the mobility of the sound limb with that which we are about to manipulate. Then, directly the patient is relaxed under the anæsthetic, every movement which the patient can perform freely and voluntarily is carried out rapidly. If any resistance is encountered we know the patient is not relaxed, and await a more propitious moment for breaking the adhesions. Once relaxation is assured, the joint is moved firmly and steadily past the obstruction. If movement has not been limited, but only painful, full movement through the anatomical limits should be performed in all directions. If movement has been limited, only those movements which have previously been free and painless may be performed to the full. As we pass the limit set by adhesions, one of two things will be noticed: either there will be a sharp crack or click, or a dull tearing, often felt rather than heard. Instantly manipulation becomes more guarded, and is carried on only sufficiently to feel that free movement is now possible past the point to which it was formerly limited. The manipulation then ceases in the direction chosen, and the process is repeated in any other direction in which movement had previously been limited. Nothing whatever is to be gained by repetition of movement in any direction, if those already performed have been carried through with necessary exactitude. To repeat a movement is a confession of doubt as to the skill with which our performance has been carried out.

The patient is allowed to come round and, as soon as possible, is called upon voluntarily to perform the movement which has hitherto been limited. If the movement is performed more freely or with less pain, the manipulation may be regarded as having been skilfully performed; if it is more limited or if pain persists for more than, say, half an hour to an extent that limits voluntary activity, then we must have grave doubts as to whether we have not been over-zealous. It is essential that properly devised exercises should be prescribed forthwith, and that these should be faithfully carried out. If any period of rest is necessary after the manipulation on account of pain, the whole success of the proceeding is jeopardised.

If the limitation of movement has been due to dense muscular adhesions, or to adhesions within tendon-sheaths, an alternative course is open to us. If we proceed as already indicated, very little progress will be made and frequent repetition will be essential. As it is usually unwise to repeat manipulation within a week, this means a prolonged and tedious recovery. It is well, then, to have an alternative method of treatment, and this is to be found in free manipulation followed by immediate fixation in plaster over *very* thick padding. The reaction is intense and pain acute, usually for several days, and nothing except morphia suffices as a rule to secure sleep. The plaster should be left untouched until the pain is definitely easing off, which usually means a delay of several days. Then it is cut sufficiently to allow the part to be massaged while still resting on the padding on the surface opposite to our manipulations. Pure relaxed movement is then performed, as for recent injury, in the direction opposite to that in which the limb has been fixed; the original posture is next restored, and the portion of the plaster removed for the manipulation is replaced in position and fixed there rigidly by adhesive plaster. The retentive apparatus is usually required for four weeks, after which it is discarded by slow stages.

THE MOVEMENT OF INDIVIDUAL JOINTS.

A few details regarding the essentials to be noted when moving individual joints call for special emphasis.

The Shoulder-joint.

When dealing with the shoulder it must be remembered that few people can, when recumbent, touch the side of their face with the surface of the arm by movement solely in the horizontal plane. The limit of normal movement in this direction depends on the position of rotation of the head of the bone, and the widest range of abduction is reached when the internal epicondyle faces directly forwards. Even so, full abduction is rarely possible without a small degree of flexion. Movement in the horizontal plane may be performed until the angle between the arm and the neck is some 30°; the limb then requires to be carried forward before it is dropped back nearly into the former plane, resting against the side of the head. Neglect of this precaution only tends to strain normal structures, and should the surgeon imagine that the normal limitation of movement is pathological a very severe sprain will be inflicted. After abduction movement has been performed the elbow is flexed to a right angle and carried forward across the chest. External rotation is performed in this position, but natural movement ceases considerably before the forearm is vertical. Abduction is then performed, combining this with both external and internal rotation, and the elbow is carried round the base of a cone of which the head of the humerus forms the apex. Until the abduction is just short of a right angle the scapula should not have moved; if it has done so it is well that an assistant should check it by pressure on the axillary border. The movement proceeds until an offending band is felt to give or until the movement has been completed as already indicated. The patient is then rolled on to his side and internal rotation is carried out until the posterior aspect of the second finger rests vertically upon the spinous processes between the scapulæ. Movement in any given direction ceases the moment any definite obstruction has been overcome. Only one other detail calls for emphasis. It is well to guard the biceps tendon with the thumb as it rests in the bicipital groove throughout the manipulation

The Elbow-joint.

When manipulating an elbow one special precaution is necessary which does not apply to the treatment of other joints. Here, too vigorous treatment is liable to meet with a disaster which is not likely to be encountered in other situations. If there has been a recent fracture in the neighbourhood, an excessive outpouring of callus is very liable to take place; while, if no fracture has previously been present, vigorous movement is liable so to damage the bone that a similar disaster is likely to follow. The greatest caution is needed when manipulating an elbow in a patient who has recently sustained a fracture through the olecranon fossa, fracture of the anterior part of the head of the radius, or a dislocation of the joint, even though X ray examination reveals no evidence of injury to bone. After fracture of the olecranon, a T-shaped fracture into the joint, or oblique separation of part of the head of the radius, less caution is called for. No special laws govern the performance of flexion, though the existence of the "carrying angle" must be kept in mind; but when extension is limited, two points of paramount importance must be regarded. First, every care must be taken to prevent the head of the radius from being pulled forward. This can be done by exerting backward pressure with the thumb over the head of the bone throughout the manipulation. Then, second, it is essential to note that the movement is performed with due respect to the "carrying angle." Unless this is done the lateral ligaments on the outer side of the joint are sure to suffer severe injury. Full extension should, of course, be secured in full supination. Far better is it to do too little when manipulating an elbow than to do too much.

Radio-ulnar and Wrist-joints.

Manipulation of the radio-ulnar joints requires attention to the fact that the movement at the lower joint differs from that at the upper in so far as it is not a pure rotation. As the lower end revolves from supination to pronation round the head of the ulna, it simultaneously glides forward. It is always well, therefore, to free the antero-posterior movement which is possible at this joint before forcing rotation. This should then be performed with firm backward pressure over the lower end of the radius for supination, and with forward pressure during pronation. The hand on the front of the wrist in this case exerts its pressure over the region of the lower end of the ulna. Unless this antero-posterior movement is secured the posterior ligament of the inferior radio-ulnar joint is liable to suffer severe damage during forcible pronation, and the anterior ligament during supination. If the obstruction is at the upper end of the radius care must be taken lest we inflict injury which will excite callus formation.

The wrist is a difficult joint to deal with as there is so much, as a rule, that requires to be done. The amount of flexion and extension that are possible vary in each individual. It is essential, therefore, to examine the mobility of the sound wrist. Pure ulnar and radial deviation are well marked and often of wide range, but (and this point is often missed) there is a very considerable amount of true rotation possible independent of the radio-ulnar joints. Finally, there is not only the radio-carpal joint to consider, but, even more important very often, there are the joints between the inter-articular fibro-cartilage and the head of the ulna above and the carpus below. In full pronation these joints are, to all intents and purposes, locked; but in supination there should be very considerable antero-posterior mobility. The loosening of these joints is often all that is necessary in order to restore perfect function to a practically useless limb. Unless they are freed no amount of manipulation of the wrist will ever restore freedom of movement or function.

Joints of the Hand.

Manipulation of the hand is a somewhat lengthy process, but it should be possible to do all that is necessary under gas. Yet time is sure to press, and it is well to have a regular routine in mind so that nothing may be missed. The first carpo-metacarpal joint is freed by grasping the thumb and exerting full tension in the long axis of the metacarpal. The digit is then carried into full abduction posteriorly and is swung round into full opposition. Great care is necessary to avoid torsion at the metacarpo-phalangeal joint during the movement. The joints between the bases of the remaining metacarpals are next freed by exerting a posterior pressure on the head of one metacarpal and an anterior on the next adjacent, and then reversing the movement. Each pair is dealt with in turn. Having done this we ensure that our objective has been secured by forming the posterior convex arch which the heads of the metacarpals can assume and flattening it out again.

Digital Joints.

Manipulation of the digits is frequently mismanaged. It cannot be emphasised too often or too strongly that the metacarpo-phalangeal and inter-phalangeal joints are not pure hinge joints. A marked gliding element is present and, unless this is regarded, the posterior ligament and probably both lateral ligaments will be torn during forced flexion. Considering the metacarpo-phalangeal joint as a type, in full extension the base of the proximal phalanx rests upon the extreme distal extremity of the articular surface of the metacarpal. If hyper-extension is possible it rests towards the posterior aspect. In full flexion, on the other hand, the situation of the base of the phalanx has shifted very considerably, and it now rests well down on the anterior surface of the bone. The nature of the manipulation required is now manifest. Little or no attempt is made to *bend* the joint. The digit is grasped firmly and longitudinal tension is applied. Abduction and adduction of the phalanx on the metacarpal are first given in each direction, then rotation is performed with the joint very slightly flexed. The lateralisation is given in full extension, but rotation is very limited in this position and only becomes free when a minute amount of flexion has been added. Then pressure is exerted anteriorly on the head of the metacarpal and posteriorly over the base of the phalanx. Instantly flexion begins. The direction of the pressure over the back of the base of the phalanx alters and tends to follow the base of the bone round the head of the metacarpal until it is exerted directly in the long axis of the metacarpal, when full flexion is reached. The movement should partake far more of the nature of movement of the head of the metacarpal on the phalanx than vice versa. The wrist, of course, should be kept in dorsi-flexion throughout. Extension is performed by reversing the process. In this way only can the ligaments be saved from tearing. At the proximal inter-phalangeal joints the tendons of the interossei are thus saved from damage—an accident which I have seen lead to almost irretrievable injury. Each joint in each digit is treated in similar manner. It is fatal to force full movement if rigidity has been serious or of long standing, or if it is in part the outcome of sepsis. In these cases movement should be performed in each direction just past the "dead point" and no more. Even though the amount of movement gained is minute, still it is enough; and it paves the way for greater gain at a subsequent manipulation. If too much is attempted the last condition of the patient is sure to be worse than before the manipulation. It is hard to avoid doing too much.

The Hip-joint.

The manipulation of the hip should always begin with rotation. This is performed with the limb lying in full extension on the couch. The knee and hip are then flexed simultaneously until the sole of the foot rests on the couch as near to the buttock as is possible, or as near as the foot has travelled after obstruction has been overcome. Abduction and adduction follow in this position. Then the limb is grasped and rotation is again performed in the flexed position, followed by circumduction as the joint is extended. The hip and the first carpo-metacarpal joint afford examples of joints which, when stiff as the result of old-standing osteo-arthritis, offer the most encouraging prognosis in treatment by manipulation. The course of the disease is not altered, but mobility is frequently increased and pain diminished. Needless to say, manipulation performed during the active stages of the disease leads to disaster.

The Knee-joint.

The most satisfactory position for the manipulation of the knee is with the patient recumbent in such a position that the end of the couch can be lowered from beneath the posterior aspect of the limb as far as the level of the junction of the middle and lower thirds of the thigh. The first essential step is to ensure that there is free lateral mobility of the patella. If firmly fixed, a not very severe strain will sometimes suffice to cause a transverse fracture. Flexion is then performed either to the limit of movement or until an adhesion has been felt to yield. A firm grip is then taken by the disengaged hand on either side of the joint just above the two tuberosities of the tibia, and the leg is rotated alternately inwards and outwards as extension is once more restored. Still maintaining this grip to guard the semilunar cartilages, the last few degrees of complete extension are added with firm pressure, so as to ensure the full locking of the joint by the final rotation of the tibia on the femur. Great care should be taken to ensure that there is no sudden jarring when the full extension is reached, otherwise the internal semilunar cartilage is liable to be injured.

The Ankle-joint.

The ankle-joint presents no special features from the manipulative point of view, save only that we must remember that little force usually suffices to effect our object and that the external ligament is very easily sprained. The chief difficulty is that the manipulation is most easily performed if the knee is flexed. Hence the best position for the manipulation is with the leg dependent over the end of the couch, or, failing this, with the patient prone and the leg vertical—a position none too easy to secure under gas. It should be remembered that flexion and extension take place in an unexpected plane—namely, in a position of apparent slight eversion. Dorsi-flexion, moreover, should be performed by tension downwards on the heel, and not by pushing upwards of the metatarsal heads. If we rely on this lever for our force the joints in the anterior part of the foot are almost sure to be strained. There is only slight lateral mobility in the ankle-joint, and this is in acute plantar-flexion. The adhesions that follow a sprained ankle commonly do not yield to manipulation of the ankle only. If the tendon sheaths of any of the tendons that pass from the leg to the foot have been involved, it is usually necessary to add manipulation of the foot-joints simultaneously.

Joints of the Foot.

The joints of the foot when stiff from osteoarthritis afford a worse prognosis as the result of manipulation than any other. Indeed, increase of mobility may yield only increase of pain on walking. On the other hand, if the disability has followed trauma and the joints are free from disease, results are frequently secured only less "miraculous" than those that follow manipulation of a knee, in which mobility has been perfect and the disability limited to occasional pain or sensation of weakness. The ankle should, in the first place, be locked in dorsi-flexion, and the os calcis is then lateralised by a firm grip on the heel. The intertarsal joints are next dealt with by performing a kind of wringing movement of the fore part of the foot upon the hind part. It is not enough to secure eversion and inversion of the foot at the subastragaloid joint; definite rotation (almost pronation and supination) of the fore part of the foot is possible. The base of the first metatarsal is endowed naturally with considerable mobility on the internal cuneiform, and particularly in the directions of dorsi- and plantar-flexion, and attention to this joint will frequently transform a well-nigh helpless cripple into one who can walk freely without pain. The laws which govern manipulation of the joints of the hand all apply with equal force to those of the foot. One small detail is perhaps worthy of notice. It is not uncommon for the "bone-setter" to claim that he cures flat-feet by manipulation. To this extent perhaps he is right—flat-foot in itself is not usually a disabling condition; it is only when mobility between the joints is impaired that pain and disability are present. Otherwise surely every ballet-dancer should be completely crippled! A "bone-setting" operation may therefore cure the pain of an early flat-foot case; it does not cure the condition. So, too, the claim is sometimes made that cases of metatarsalgia can be cured by manipulation. Again there is a germ of truth hidden beneath an unlikely statement. Sometimes it will happen that a patient with this trouble will trace its origin to a definite occasion on which he trod on a pebble, or walked over cobbles in thin shoes. His pain may be that of metatarsalgia; but, on examination, the anterior arch is not found to be "broken" unduly and there is no pain on pressure, only on movement. Then manipulation offers every prospect of cure, as the trouble has originated in a simple traumatic arthritis. Anæsthesia may not be required for the "cure."

Little need be added on the subject of breaking down adhesions that are due to trauma of muscles or of tendon sheaths. The chief thing to remember is that no harm is done by doing too little; severe injury is always inflicted if we do too much. Repetition of the manipulation is also frequently advisable.

TRAUMATIC LUMBAGO.

One word remains to be said concerning the so-called "traumatic lumbago." The victim is not a malingerer, though often he is dubbed as such. The disability is very severe; if the origin is due to adhesions following rupture of a few muscle fibres, the treatment fortunately is easy and usually satisfactory. The patient is given a general anæsthetic, and is placed fully recumbent. The hip of the less painful side is fully flexed into the abdomen and is again placed by its fellow. The process is repeated on the opposite side. Then both hips are flexed together on to the abdomen, flexion of the knee in each instance coinciding with the flexion of the hip. When the anterior surfaces of the two thighs are as far as possible in contact with the abdomen the sacrum is raised well away from the couch. The pelvis is then waved freely from side to side as the extreme flexion is slowly relaxed, and rotation of the spine is performed. When lateral movement is no longer possible without dragging the sacrum from side to side on the couch the patient is placed fully recumbent once more, and the hands are passed round the trunk till they meet in the mid-line behind. Then firm traction is exerted forwards as if attempting to raise the whole weight of the body. A considerable arching of the back is thus secured, and lateralisation is administered as the traction is relaxed and the recumbent position is slowly restored. "Traumatic lumbago" is frequently due to a slight tilting of one ilium on the sacrum. The pain can be relieved almost spontaneously by treating the patient prone. One hand is placed over the region of the posterior superior spine and exerts downward pressure, while the other forcibly pulls the thigh backwards.

The cervical region is sometimes affected in similar manner, or symptoms (neuralgic pains in the back of the head and neck, and even brachial neuritis) may be described in the absence of a history of definite injury. There is no call for anæsthesia for the performance of the manipulations. The patient is placed recumbent, with the head and neck projecting freely over the end of the couch. The head rests upon the manipulator's hands, and the main point that calls for attention is that tension should be given by securing a firm grip either of occiput and mastoid on each side with one hand, or of occiput with one hand and chin with the other—a grip corresponding to that of the collar in ordinary head suspension—before the movements of flexion, extension, lateralisation, and rotation are performed.

At the other end of the spine we meet with that troublesome and often intractable complaint, coccidynia. Sometimes this can be relieved by manipulation, and sometimes it fails. The forefinger must be passed into the rectum, and each joint is then manipulated in turn. In addition to the pure flexion and extension a slight twisting movement should be added. Care must be taken not to be too severe in carrying out the manipulation.

There is no "mystery" in the art of "bone-setting." Certain details require attention and nothing more. We must know what the natural movement of the joint is, we must realise its limits, we must avoid laying any strain whatever on any normal structure—under anæsthesia there is no protective reflex to save it from harm—and all will be well. But under anæsthesia nothing is more simple than to damage normal structures, and then we have to face the unpleasant necessity of dealing with a sprain of our own creation. It is often an easy matter, when administering forced movement without an anæsthetic, to strain severely any muscle that is thrown into reflex protective spasm during the manipulation.

If our object is to relieve pain or secure increased mobility, we have failed if either of these two objects fall short of attainment. In mobilisation under anæsthesia we have very often an excellent example of the fact that in many cases we do not cure, but depend on the patient's voluntary coöperation before the end is achieved. Manipulation will often suffice to cure pain alone, but it is rarely enough to restore movement. After mobilisation the patient must be taught how to improve his mobility as the result of voluntary effort, and without skilled teaching and cordial coöperation the whole procedure may be rendered void and of no effect, for the adhesions will quickly re-form. It is for this reason that severe pain after manipulation should be regarded as an indication of failure. The pain inhibits voluntary action, and without this recovery is well-nigh hopeless. Unless the patient owns up to greater comfort or more freedom within an hour or so of the manipulation, too much has probably been done.

APPLICATION OF PRINCIPLES ENUNCIATED TO TREATMENT BY MASSAGE.

The application of the principles already laid down to manipulation in the massage-room is simple. In the first place, the anæsthesia of forcible manipulation has as its object relaxation of the antagonists that oppose the movement we wish to perform. In massage this place is taken by "active relaxation." As soon as pain is felt this relaxation is supplanted by reflex spasm of the antagonists, which can only be abolished by calling upon the muscles which control the movement to contract. This, of necessity, causes reflex relaxation of the antagonists. In the massage-room, therefore, forced movement should always partake of the nature of assistive movement. Far better is it to assist the action of a muscle than attempt to stretch or tire out its antagonists. There should be no excuse for confounding forced movement with passive movement. The latter can only be administered when the patient's muscles are in a condition of complete voluntary relaxation, and when there is no perceptible obstacle to movement.

The laws which govern the direction in which manipulation is to be given are, of course, identical in the two cases. Only one word is necessary. When applying tension the greatest care should be taken not to let the grasp slip. The grip, in other words, must be very firm. The manipulation must be performed smoothly and with even pressure; there must be no aimless waggling to and fro and no spasmodic jerking. The pressure must be released as smoothly and gradually as it was applied.

In order that the patient may be in the most favourable attitude to contract his antagonists, the position in which he is placed in the massage-room as a preliminary to the administration of forced movement is not always identical with that chosen when the manipulation is to be performed under a general anæsthetic.

Thus, for instance, flexion of the knee is often best performed with the patient on his face, and the foot is often manipulated to best advantage while the leg rests on the masseur's lap. Shoulder and elbow are best treated absolutely recumbent.

AFTER-TREATMENT.

The after-treatment of cases that have been treated by mobilisation under an anæsthetic varies with the condition found. Restoration of function being the objective, active movement must be prescribed at the earliest possible moment. This should be within a few hours of the manipulation, and, if possible, within a few minutes. But all manipulations must be regarded in the light of the infliction of injury. If pathological tissue has been broken down—the picture is far different if it has been severely stretched only—the injury, as a rule, is trivial, and we can proceed apace. If pathological or normal structures have been stretched, reaction varies with the amount of damage done. It may only be very slight. On the other hand, if manipulation has been too vigorous, or if it has been unskilfully performed, then the structures around the joint—ligaments and tendons—and the muscles that control the movements of the joint have suffered injury, which may amount only to slight strain, to sprains of all degrees of severity, until finally we come to the by no means unknown catastrophes, torn muscles, tendons or ligaments, or even dislocation and fracture. Obviously treatment must vary with the extent of the damage done, and this can only be gauged by reaction. To expect a masseur to put a joint through its full range of movement merely because this has been done under anæsthesia is utterly preposterous, unless, indeed, we have the certainty that no strain has been placed on any non-pathological tissue. So rarely, however, is this the case that the full range of movement is rarely attainable for two or three days unless there was little or no previous limitation. Each case must be treated individually, and the laws which govern all treatment of recent injury must be respected.

DENTAL SEPSIS IN CHILDREN:

ITS CONSEQUENCES AND TREATMENT.*

BY F. ST. J. STEADMAN, D.P.H., L.R.C.P., M.R.C.S., L.D.S.

AMONG the many lessons which the war of the past five years has brought home to us is the important fact that the physique of our race is by no means as good as it ought to be; indeed, the Prime Minister, in a speech last year, stated that the physical examination of recruits had revealed an appalling state of affairs. Among cotton weavers, for example, only 19·6 per cent. of those examined were placed in Grade 1. In one day's batch of 59 men, only 3 were found to be in a fairly good physical condition. A struggle for our very existence as a nation, such as that through which we have just passed, brings home to us the gravity of this matter in a way that nothing else can.

The causes of this deterioration of our national physique are doubtless many. Civilisation entails the performance of a large amount of work in a vitiated atmosphere; while diseases such as tuberculosis, rheumatism, and valvular disease of the heart are rife. It is the duty of the medical profession (in which I, of course, include the dental) to determine as accurately as possible where we are at fault, and to strive against those conditions which impair the health and strength of the community.

The Medical Society of London has commenced this investigation, but judging from a report of a meeting held on Nov. 25th, 1918, in which the causes of rejection were classified and in which there is no mention made of dental disease, the Society is, once again, overlooking the commonest cause of deteriorated physique. When we realise the prevalence of dental disease in all classes it is strange that, even to-day, the medical profession does not appreciate its vital effect on the physique of our race. Dr. J. D. Comrie states that of 10,000 recruits 928 had artificial teeth, while another 1120 had lost half their teeth at least, and that a septic condition of the teeth with deposit of tartar and gingivitis was frequently associated with dyspepsia and invariably with a deteriorated physique.[1]

I think it will be generally admitted that chronic disease in childhood, the effects of which spread over a period of years, must have a profound influence upon mental and physical growth. Of all chronic diseases of this character, dental disease is by far the most common, as something like 80 per cent. of the children of the race are suffering from dental diseases.

I assume that we are all agreed upon the tremendous importance to the child of a perfect dental arch; that the best way to combat dental diseases is by prevention with the necessary prophylactic measures, a clean mouth in, and the proper feeding of, the pregnant mother, breast-feeding in infancy, the establishment of proper nasal breathing, and proper diet—a diet requiring efficient mastication. Further, that we are agreed upon the immense importance of early and constant dental supervision, so that caries can be treated early, either by silver nitrate or, when the cavities are shallow and do not involve the pulp, by suitable fillings; that it is generally a reflection upon the parents, and more especially upon the dental adviser (provided that his inspections have been sufficiently frequent) if a pulp is allowed to become infected or if treatment is delayed until infection of the pulp has occurred. I want to emphasise these points because it has been said that I do not believe in the conservative treatment of teeth in children. I want to make it quite clear that I do all I can in my practice to conserve the deciduous as carefully as I do the permanent teeth.

I propose in this paper to deal with the effect of marked dental sepsis on the health of children, and with the treatment of those all too common cases in which the prophylactic and remedial measures just enumerated have not been carried out, and the child has been brought to us with advanced caries in one or many teeth. Moreover, I want it to be clearly understood that I have in my mind the treatment of this sepsis from a broad national point of view. I am not concerned so much with the treatment of the children of the rich, for although, of course, the fundamental principles are the same for both, it is clear that in dental diseases, like all other diseases, there is often one means for the rich and another for the poor. The advice given to a wealthy, leisured mother (who is aided by nurses whose sole work is to look after her children) may be different from the advice given to the busy working-class mother, whose day's work begins when she gets up in the morning and ends only when she goes to bed at night. It is as futile to tell such a mother with five or six children that she must see that they clean their teeth carefully after every meal with a toothbrush, aided by floss silk, as it is for a physician to order the bread-winner of a family, earning £3 a week and suffering from phthisis, to take a 12 months' sea voyage.

The Effects of Dental Sepsis upon Children.

The effects of dental sepsis upon children can be considered under two main headings: (A) General; (B) Local.

(A) *General.*—It was during my work at the Belgrave Hospital for Children some years ago that I first began to appreciate the profound effect that dental sepsis may have upon the general health of the sufferers. When I first took up this work I thought that the pale-faced, tired-looking, under-weighted and mentally inefficient children whom I saw were the result of semi-starvation, due to poverty. One day, however, I happened to notice a mother who had brought such a child to me and who had with her another of her children, who had not this half-starved appearance but who looked healthy and well. Thinking that this marked difference in appearance might be due to favouritism on the part of the mother, I questioned her closely, but found that her treatment with regard to the food of both children was the same. I then looked at the mouths of the two children. My little patient was suffering from advanced caries, with its consequent gingivitis, while the mouth of the other was healthy. I removed the septic teeth from the one, and a few months later it was as healthy in appearance as the other. This very common and ordinary case illustrates very well the effect dental sepsis frequently has upon children. Mental and physical growth is retarded. Pale-faced and anæmic, their eyes have not the normal lustre of healthy children, and they have a tired and sleepy look about them.

Sir J. F. Colyer was, I think, the first to weigh these children before and after treatment, and in a paper read before the Manchester Odontological

---

* Read before the Odontological Section of the Royal Society of Medicine, Jan. 26th, 1920.

[1] THE LANCET, Nov. 29th, 1919.

Society on Dec. 6th, 1910, gave the weights of some of the cases he had treated for sepsis. He showed that there is frequently a marked increase in weight, too great to be accounted for by the normal increase of growth. He gave details of the following four cases:—

M. L., aged 4 years 6 months. When first seen was suffering from gastro-intestinal trouble. Teeth removed $\frac{\text{DCBA}\,|\,\text{ABCD}}{\text{ED}\ \ |\ \ \text{DE}}$. In this case the $\frac{\text{E E}}{}$ were not carious and were retained until the $\frac{6\,|\,6}{}$ erupted. This patient lost her gastro-intestinal trouble, and between June 8th and Oct. 2nd, 1909, increased in weight from 2 st. 4 lb. to 2 st. 8 lb. The normal weight should have been 2 st. 8 lb., and the normal increase in four months 1½ lb. This patient increased 4 lb.

W. G., aged 7 years 4 months. Stated always to have indigestion. Teeth removed $\frac{6\text{EDC}\,|\,\text{CDE}6}{6\text{EDC}\,|\,\text{CDE}6}$. The teeth were removed on Dec. 6th, 1909, the patient weighing 3 st. 2½ lb. On Feb. 7th the weight had increased to 3 st. 5 lb. and all symptoms of gastro-intestinal trouble had ceased. The average weight of this boy should have been about 3 st. 9½ lb., and the increase in two months a little under 1 lb. The weight, however, increased in two months 2½ lb.

A. R., aged 6 years 7 months. Complained of constant feverish attacks. Teeth removed $\frac{\text{EDBA}\,|\,\text{ABDE}}{\text{ED}\ \ |\ \ \text{DE}}$. Between December, 1909, and Oct. 23rd, 1910, the weight had increased from 3 st. 5 lb. to 3 st. 10 lb. The feverish attacks had ceased and the child was sleeping and eating well. This patient was about average weight, and the increase in weight about normal.

The rapid increase in weight following extraction is at times very marked.

For example, in his fourth case a boy, aged 10 years 2 months, it was found advisable to remove $\frac{\text{EDC}\,|\,\text{CDE}}{\text{EC}\ |\,\text{CDE}}$. Between June and October this boy increased from 4 st. 6 lb. to 4 st. 11 lb. The normal weight should have been about 4 st. 11½ lb., and the average increase in four months about 2 lb. This child in the period increased 5 lb.

I have weighed a considerable number of children, and have been able amply to confirm Sir James Colyer's results. As he points out, the increase in weight is not always shown. In a few cases there may even be a slight decline. This is frequently traceable to sepsis in other parts—for example, tonsils or nasopharynx.

One of the chief ways by which dental sepsis in children produces this loss of mental and physical growth is by the reduction of sleep. A careful investigation of the history of these cases will frequently disclose that for months and months the child has not slept well. Its nights have been disturbed by pain. This important symptom has to be looked for, as children do not as a rule complain of it. When one considers the effect of a series of bad nights upon oneself, the importance to the child of this lack of sleep can be dimly realised. I wish to emphasise this point with all the power that I can. Its importance cannot be exaggerated.

Some years ago the father of one of my young patients at the Belgrave Hospital for Children took the trouble to find out where I lived to visit me for the purpose of thanking me for my treatment of his son, aged 9. Some 14 months before I had removed his 12 molar teeth, $\frac{6\text{ED}\,|\,\text{DE}6}{6\text{ED}\,|\,\text{DE}6}$. The father told me that up to that time the boy had always been delicate and ailing. He had had many restless nights from toothache and had constantly needed medical care. He was small, under weight, pale-faced, and very backward at school. He had "suffered terribly." A few days after the operation he began to change rapidly. He has now rosy cheeks, looks well, has regained his normal weight, has not once been ill, and has made rapid strides at school. It seemed, as his father said, as though a millstone had been removed from about his neck.

Gastro-intestinal Disorders following on Oral Sepsis.

A common result of oral sepsis in children is gastro intestinal disorders, as evidenced by gastric and abdominal pain, diarrhœa of an offensive character, with much undigested food in the motions, marked wasting, fretfulness, night-terrors, loss of appetite, sleeplessness, and pallor of the face. In treating a case such as this, it would appear to be a common-sense thing to do first to inspect the mouth and to remove any possible source of infection in it before proceeding to treat the stomach; yet many medical practitioners still neglect to do this. In one case of this kind which came under my care, a child, aged 7, had been treated for no less than 14 months by her doctor, who had made only a very cursory oral examination. Indeed, as the child was frequently awake at night with toothache the mother had more than once asked him whether he thought that the condition might be due to the teeth, and whether he thought it advisable to have the teeth treated, but the doctor had replied that the teeth must on no account be removed, because that would injure the permanent ones, and, moreover, would prevent mastication! At last the mother, finding that the doctor's medicines did no good, determined to have the teeth attended to. On examination I found advanced caries with exposure of nearly all the pulps in $\frac{\text{EDC}\,|\,\text{CDE}}{\text{ED}\ |\ \text{DE}}$ with definite chronic abscesses over $\frac{\text{D}\,|}{\text{E}\ \ |\,\text{D}}$. Three or four weeks after the removal of these teeth the child was practically well.

This gastro-intestinal condition is due to sepsis and not to lack of mastication, as proved by the fact that the cases frequently get well very soon after extraction of the teeth, and almost before the gums have healed—that is to say, while the gums are still too tender to allow of mastication upon the teeth that remain. This is borne out, I think, by the most interesting observations of Dr. H. Waller upon dental disease in nursing women. He shows that in many instances in which a breast-fed baby ceases to thrive while still at the breast, the trouble can be traced to sepsis in the mouth of the mother. He gives details accompanied by charts of three cases selected from nearly 200, demonstrating the marked gain in weight of the infants after the extraction of septic maternal teeth.[2]

In these cases it is clear, I think, that the digestive apparatus of the child is unchanged; that the improved health has been brought about by the removal of sepsis in its food. Similarly, as Dr. Sim Wallace points out, anæmia of other than dental origin is liable to be aggravated by the chronic toxæmia and septic absorption which may be associated with dental sepsis.[3] Other chronic diseases, such as tuberculosis, cannot but be prejudicially affected by an insanitary state of the mouth. Typhoid and scarlet fever and other zymotic diseases have been shown by Hunter to be much more dangerous when dental sepsis is present.[4] Further, sepsis from the mouth may be absorbed into the blood stream, giving rise to such diseases as septicæmia or endocarditis.

[4] Oral Sepsis as a Cause of Disease in Relation to General Medicine, Brit. Med. Jour., 1904, ii., p. 1358.

(B) *Local.*—Under this heading I include the adjacent parts to which infection sometimes spreads by continuity of tissue. Pharyngitis, tonsilllitis, otitis media, and—much more rarely—meningitis and such-like troubles. Infection may pass down the lymphatics to the submaxillary and cervical glands. Some hold that glands are so commonly enlarged in children that it is not worth while even examining for them. In my opinion, such teaching is absolutely wrong. I think (although I know that I am on controversial ground) that normally the submaxillary and cervical glands are not palpable in children; that if they are, there is sepsis somewhere. Carious teeth frequently produce enlarged glands, as proved by the fact that these glands disappear after the removal of the teeth. At the same time, I am well aware that we see enlarged cervical glands in children with perfectly clean mouths.

Enlarged Glands in Children.

We dental surgeons are apt to forget that these glands drain a very large area apart from the teeth and oral mucosa. For instance, the tonsils, the nasopharynx, the orbits, the skin of the face, the anterior part of the scalp, &c. We also commonly see children with very septic teeth in which the glands are apparently not affected, but as Mr. G. Morgan points out, this freedom from injury to the gland is often more apparent than real:—

> "A gland constantly irritated by micro-organisms from a carious tooth is potentially weaker; it is more vulnerable than a gland not so irritated. This greater susceptibility to injury is shown by the effect of strain on such glands. I think we may take it for granted that a gland becoming tender and remaining for some weeks enlarged from a simple strain is not a healthy gland. Its resisting power has been lowered by having to deal with micro-organisms, perhaps in no great amount, and I think one may say of low virulence, but spread over long periods. A girl, aged 8, coming of a very healthy family and living in a good house, slipped whilst using dumb-bells and strained the muscle of her neck. The next day there were two tender glands a little in front of the right angle of the jaw. The six-year-old lower molar on this side was badly decayed and had been so for a year, yet until the strain there was no sign of enlarged or tender glands. After the strain the glands remained enlarged for several months, and one finally became tuberculous. Glands in the groin will sometimes enlarge from the strain of football, but careful examination of the area of drainage and going into past history will nearly always prove that the glands were not in their normal state at the time of injury. Measles and whooping-cough often play the same rôle as strain—i.e., glands injured by carious teeth, and yet not visibly showing any change, will enlarge more quickly and remain enlarged longer than glands not so injured. I could supplement these cases by others, proving that strain alone does not cause inflammatory enlargement of healthy glands."[5]

It should be remembered that a very slight septic focus in children will often lead to enlarged glands, and if glands are palpable we should endeavour to find the cause. It is true that the glands often rapidly diminish in size after the removal of septic teeth, but they do not always quite disappear. They appear to be fibrosed, and years later, at the age of puberty, they occasionally break out again, and examination may show them to be tubercular. Occasionally these infected glands break down, and the infection is carried to other parts of the body, giving rise, possibly, to tubercular lesions in the bones, or it is even possible that tubercular meningitis may be set up. Mr. J. G. Turner has shown that sepsis in the deciduous teeth not uncommonly leads to damage of the permanent teeth beneath them, as shown by hypoplasia and some of those deformities which have been classed under the term dilaceration, commonest among the premolars and fairly common amongst the incisors. I have examined a number of radiographs of the bone round septic teeth to ascertain whether any rarefying osteitis is to be observed, especially in those cases in which the pulps have died under fillings. I am not able to make a definite statement upon this at present, but hope to bring this point up again on a future occasion.

Lastly, the carious tender teeth by disuse bring about a gingivitis which may spread eventually to the periodontal membrane of the permanent teeth, with all its consequent ill-effects upon the health of the individual. Many of our citizens, owing to neglect of their teeth in childhood, have had dirty septic mouths all their lives, so that we need scarcely wonder at their poor physique.

Such, then, is a by no means complete picture of the possible consequences of sepsis in children and upon the national physique. No doubt one frequently sees children with exceedingly septic mouths apparently in robust health. I have reason to suspect, however, that in some of these cases, at any rate, this robust health is more apparent than real. Then arises the interesting question, What percentage of children with marked sepsis in their mouths have their general health thereby affected? It is a question which I fear in the present state of our knowledge we cannot answer, but one worth trying to solve in the future.

I have treated between 7000 and 8000 children in the way that I am about to describe, but these have been mostly hospital patients; consequently I have only been able to follow up a comparatively small number. Of these I can definitely state that a considerable percentage have shown marked improvement in their general health, and none whose health has been adversely affected by the removal of their septic teeth. The illustrative cases I am giving are merely examples of very many others of the same kind which have come within my experience.

Would that I had the power of a Raemaker in depicting these things graphically! I would draw a picture showing the enormous number of children of our race wrapped in a pall or dense fog, the fog of dental sepsis, retarding their mental and physical development. Drastic treatment of this sepsis is like snatching away the pall or lifting the fog. Normal weight is regained, their eyes once more shine brightly, and the palest cheeks become rosy. These children have been given a chance to grow.

The Treatment of Dental Sepsis in Children.

All deciduous teeth in which the decay is sufficiently advanced to infect the pulp I extract, and generally their antagonists also. I only fill teeth when I feel sure that the pulp is not affected. This condemns at once the majority of decayed deciduous teeth, because the pulps of these are relatively larger than the permanent teeth, so that a comparatively small cavity is sufficient to infect the pulp. By infected pulp I do not necessarily mean an exposed pulp. Many pulps are infected long before the actual exposure has occurred.

I treat the permanent molar teeth in the same way as the deciduous teeth if the roots are incomplete at the time of the pulp infection. I know of no way of dealings with infected pulp in children which I regard as sound. The treatment recommended by many practitioners of sterilising and capping the pulp is, in my judgment, dangerous, as in the majority of cases so treated the pulp eventually suppurates and dies under the filling, and the teeth remain tender and uncomfortable, so that the child's confidence in them is not restored and he does not use them for the purpose of mastication; frequently they ache and he remains with his disturbed nights. The following case which came under my care illustrates these points:—

---

[5] Lymph Glands in Relation to the Teeth and Gums, British Dental Journal, August, 1903, p. 522.

[6] Injury to the Teeth of Succession by Abscess of the Temporary Teeth, Brit. Dent. Journ., 1909, p. 1235.

The patient was a boy, aged 5, and was brought to me by his mother on account of pain in his teeth, which caused him to have restless nights. On examination I found he had no less than 11 amalgam fillings inserted into his deciduous molars. Three of these teeth $\begin{array}{c|c} & E \\ \hline E & D \end{array}$ were obviously dead and tender, and pus could be squeezed out from the pockets around them. The gums all round the mouth were inflamed and dirty. It was clear that the child had not used these teeth for the purpose of mastication for some time. The submaxillary lymphatic glands on either side were swollen and tender, as also were the cervical glands on the left side. The mother said the child never seemed well, was always irritable and cried himself to sleep when put to bed, and frequently woke during the night, at such times complaining of pain in his teeth; that he had not had a good night's rest for months, and that he did not care for his food and did not eat enough. The child's general appearance amply bore out his mother's statements. He was small for his age, pale-faced, and his eyes lacked the brightness and intelligence of the normal child. The dentist who filled these teeth had told the mother that nothing further could be done until the child was aged 10 or 11, when these teeth would be shed, and that it was absolutely necessary to retain them for the purpose of mastication. A second dentist had confirmed this opinion. In the face of these opinions of two of my fellow practitioners, I had some difficulty in getting the parents' consent to the immediate extraction of the deciduous molars. Fortunately I was supported on this occasion by the family doctor (more often than not, I regret to record that I have found in him a strenuous opponent). The operation was performed on March 8th, 1913. The effect was startling. On that night and each following night the child slept well; there was no crying out and no restlessness whatever. On April 22nd the glands were only just palpable, and were no longer tender, and the beneficial effect of the good nights on the child was obvious. The pallor of his cheeks and the sleepy, tired look had vanished. The mother said that the improvement in health "seemed marvellous" and the child was "altogether brighter in himself." He was eating well and seemed always to be hungry. This child was not weighed, but it was apparent that he was steadily putting on weight.

The Effect of Extensive Extraction in the Area of Mastication.

The argument against extensive extraction in children, that mastication is lost, is futile. I cannot understand how it is that medical and dental practitioners who use this argument can fail to see for themselves that mastication is already lost. No child will masticate on tender teeth and exposed pulps; but one may actually take up the other line of argument and say that by the removal of tender teeth the area of mastication is increased. An exposed pulp in a deciduous molar means that the child will not masticate on that side of the mouth, so that the important six-year-old molars behind them are not functional; remove the tender tooth and these teeth will be restored to usefulness.

Experience shows that the child regains its normal weight and health after extraction of all septic molars. In other words, experience shows that it is better for the child, if food has to be bolted, that the food be as clean and as uncontaminated by pathogenic organisms as possible. Here, in passing, I would like to point out that if it has been decided to extract the six-year-old molars it is best to do so early, when the child is about 10 years old, and not wait until the 12-year-old molars have erupted, so as to allow these latter teeth to come forward.

If you take 30 children and arrange them in a group, and 10 of these children have all of their teeth present and their teeth and mouths perfectly healthy, and 10 have had most or all of their teeth removed but their mouths otherwise healthy, while the remaining 10 have septic teeth and inflamed gums, it will be easy for the trained eye—aided, if you like, by the weighing machine—to pick out these last 10 children, but it will not be possible to separate the remaining 20.

Effect of Extraction on Development of the Jaws and the Permanent Molars.

Another argument against the extraction of teeth is that it prevents the proper growth and development of the jaws. If the extraction of teeth adversely influences the growth of the jaws it is clear that if several teeth are removed on one side and not on the other, the jaws on the one side from which these teeth have been extracted will show a deficient growth; whereas, the side from which the teeth had not been removed will grow normally, giving the whole face a lop-sided appearance. Experience shows that save in exceptional cases nothing of the kind happens; on the contrary, the jaws still reach their normal development on both sides, in spite of the loss of the teeth on the one side. Or again, if we extract teeth from the upper jaw and not from the lower, it has been said that the upper jaw will not grow properly but the lower will, so that we shall have brought about an "inferior protrusion," or vice versa; but nothing of the kind happens, showing that the normal growth of the upper jaw has apparently not been affected by the extraction of the teeth.

A more important argument which requires attention is that the early extraction of deciduous teeth will lead to the forward movement of the six-year-old molars, thus causing crowding and irregularities of the arch later on. If the teeth are extracted before the permanent molars have occluded, there is no doubt that this will take place, but, provided the patient comes frequently for dental inspection, at the right moment one of the permanent teeth in each corner of the mouth can be sacrificed. These teeth may be either the four six-year-old molars or the four premolars, according to circumstances. If the extractions take place after the permanent molars have occluded, there will be very little forward movement.

Importance of Removing Antagonists.

I have said that I remove, as a general rule, not only the carious teeth, but also the antagonists. The importance of this was brought home to me by a demonstration by Colyer at one of the "At Homes" of the Royal Dental Hospital some years ago. A young child who had one lower deciduous molar tooth missing but all the rest of the teeth present and healthy, was given a meal of soft food (bread-and-butter) and was then given an apple. The eating of the apple mechanically cleansed away all the soft food which remained around the teeth after the meal of bread-and-butter, except that around the tooth which was opposite the place where the tooth was missing. Around this tooth was a soft film of carbohydrate food, and when this was scraped off, a little ring of inflamed gum all around the tooth was seen, due to the frequent lodgment of food. This, to my mind, clearly demonstrates the importance of removing this functionless tooth, for if left it is liable, owing to the tenderness of the gum around it, to prevent mastication and to force the child into the pernicious habit of unilateral mastication. In those cases, however, in which the four lower deciduous molars and the first upper are carious but not the second upper deciduous molars, I leave the latter (in children aged under 6) in position, following the teaching of Colyer, until the permanent molars have erupted and occluded.

I think we do not realise sufficiently the importance of preventing unilateral mastication. It means that on the unused side we shall get a marked gingivitis, and more important still, this habit is liable to become permanent, so that later on, when the permanent teeth have erupted, they quickly become septic also. I am convinced that many cases of periodontal disease can be traced back to tender teeth in the child.

The Expediency of Free Extraction.

There is another argument in favour of extraction which, however, I bring forward with some hesitation—that of expediency. One would, perhaps, hardly be justified in acting upon expediency alone were it not supported by the other and more powerful arguments that I have already given.

Of the 7,000,000 or so children in this country, something approaching 6,000,000 require dental aid. I think if I allow, on an average, one hour's work for each child to do what is required, I shall not be accused of overstating the case. If this work is carried on at the rate of five and a half hours a days, it will take one man nearly 3000 years to complete. This rough calculation will show that we have nothing like enough dental surgeons to get through the work. On the other hand, if we extract all teeth with infected pulps, a tremendous amount of time will have been saved. It is difficult to estimate the beneficial effect this work would have upon the health of the children, and consequently upon the physique of the nation; although it is true we should have a greater number of crowded arches to deal with. A result cheap indeed at the price. Of course, there is no doubt that as the years go on this huge mass of dental work in children will gradually lessen as the teaching of prevention becomes diffused in the schools.

It takes a considerable amount of courage to condemn a large number of teeth in a child. This necessary courage can only be acquired by observing, recording, and pondering over the evil consequences of leaving these septic teeth. A proportion of the dental profession at the present day appears to lack this courage, or have not yet realised sufficiently the great harm they are doing to their patients by leaving septic teeth. Four times during the past six months parents have brought children to me simply and solely because they have heard that I am willing to treat children. One case was a boy, aged 5, in which every tooth in the child's mouth was carious almost down to the gum margin, causing a septic gingivitis and profoundly affecting his health. The father told me that he had taken the child to two dentists and a doctor, each of whom said that nothing could be done. The father told me that common sense convinced him that something could and ought to be done. Removal of all the deciduous teeth has had a very marked beneficial effect upon this boy's health, but will no doubt lead to crowding later on and the sacrifice of four permanent teeth. I have explained this to the parents, but they do not seem to think that this is worth considering in face of the immense improvement in the child's general health, an attitude which I cordially endorse. In another case a little boy was brought to me with a large swelling in connexion with his left lower deciduous molar. A doctor had treated this for eight weeks, stating that the tooth, being a temporary one, must on no account be removed. During this time the swelling on the jaw had become hard and brawny; pus had burst through the skin, and when I came to remove the tooth I found a large piece of necrosed bone at the bottom of the sinus. Had the tooth been removed eight weeks sooner the patient would have been spared permanent disfigurement.

The Treatment of Children.

It is true that a considerable number of dentists do not wish to treat children. It is not given to everyone to have the patience and tact that is necessary to deal with young children, but if a practitioner has not these qualities he should manfully recognise the fact and send children to those who will undertake their treatment.

The ignorance of a small but harmful minority of medical practitioners concerning dental matters is, without exaggeration, nearly as great as that of the general public. These men cannot yet appreciate their own ignorance and sometimes give advice on dental matters, which is not only wrong but often positively extremely harmful. Progress is being made, but it is slow. In the war against dental disease and its train of consequences, in the effort to snatch off the pall and clear away the fog of sepsis which envelops our children, I have sometimes thought that these medical practitioners are like evil spirits, doing there utmost to prevent the clearance of that fog. On more than one occasion when I have urged the removal of abscessed teeth which are keeping their possessor awake night after night with pain, besides causing severe general ill-health, the medical adviser has stepped in and said that nothing must be done to the teeth until the child's health has improved. It is difficult to follow what is in the mind of the giver of such advice. What would one say if, when his house was burning, the firemen told him that they must wait until the heat had cooled down a bit before they commenced to put it out?

Lastly, I would like to emphasise one more point, which I consider very important—namely, that if extensive extraction has been decided upon, it should be carried out at one time under one general anæsthetic such as ethyl chloride. In this way we put much less strain upon the nerves of the little patients. In one case which came under my observation a dentist had condemned 12 septic teeth and proceeded to remove them, one at a time, under gas. After five teeth had been removed in this way the child's nerves had been shattered. I can see no great objection and very little risk in removing all that are necessary at one operation.

PAUCHET'S METHOD OF GASTRECTOMY.

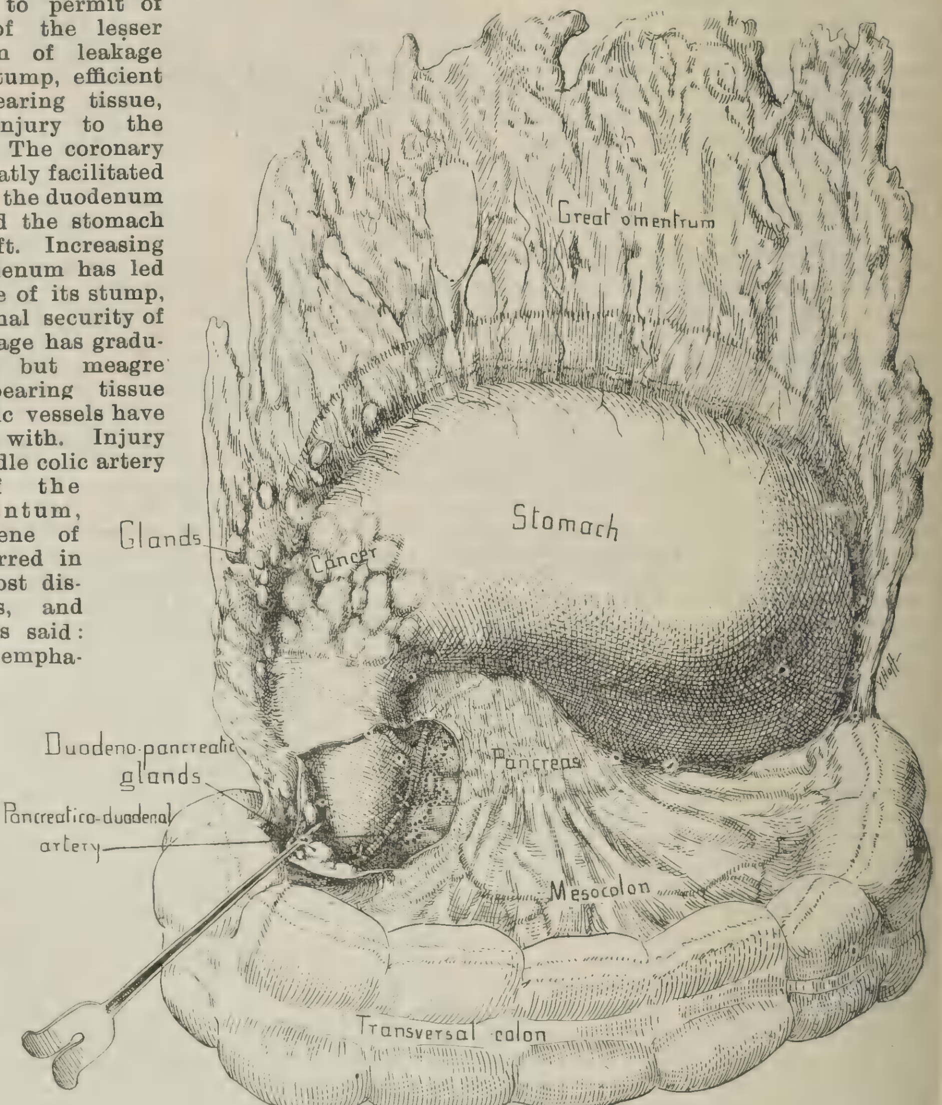
By IAN MACDONALD, M.D. Edin., M.D. Paris.

In cancer of the stomach competent surgeons have insisted that the radical operation should always when possible be performed. In their expert hands wide pylorectomy shows a steadily diminishing mortality and in many cases offers a reasonable prospect of cure. Should the operation prove only palliative the comfort of the patient is greater than if left with his tumour after a simple gastro-enterostomy. If, then, gastrectomy can be simplified, it will be more often performed, and the easy short-circuiting operation will be reserved for the limited number of cases in which it is useful. The principal technical difficulties of resection in cancer are high ligation of the coronary artery to permit of adequate removal of the lesser curvature, prevention of leakage from the duodenal stump, efficient removal of gland-bearing tissue, and avoidance of injury to the middle colic artery. The coronary ligature has been greatly facilitated by leaving it till after the duodenum has been divided and the stomach swung over to the left. Increasing respect for the duodenum has led to very careful suture of its stump, and with the additional security of an omental flap, leakage has gradually become rarer; but meagre removal of gland-bearing tissue and danger to the colic vessels have still to be reckoned with. Injury or ligature of the middle colic artery during division of the gastro-colic omentum, resulting in gangrene of the colon, has occurred in the hands of the most distinguished surgeons, and as one of them has said: "It is impossible to emphasise too strongly the need for care and caution in this matter." The initial step in Pauchet's method of gastrectomy ensures the integrity of this vessel and provides fully for removal of infected gland tissue. The steps of his operation are as follows:—

Technique of Pauchet's Operation.

1. *Omental colic separation.*—Pauchet applies the technique used in France by Lardennois and Okinczyc as the first stage in colectomy to the surgery of the stomach. The great omentum and transverse colon are lifted out of the abdomen through a median incision above the umbilicus. The line of attachment of the omentum to the colon is shown by a series of most delicate vertical pleatings. The assistant, lifting up the great omentum with his right hand, on the flat of which rests the spread-out omentum, with the left gently pulls the colon downwards. The operator, holding the omentum in his left hand, passes the point of a very sharp knife along the pleated attachment, beginning this fine bloodless dissection well over towards the left of the patient. The cleavage area soon appears and is enlarged within a compress. Commencing on the colon, it continues along the mesocolon, through an avascular space bounded below by the transverse mesocolon, easier to define as the separation goes farther back to where the mesocolon is implanted on the posterior abdominal wall. The omentum can finally be thrown upwards with the stomach, leaving the posterior surface of the stomach, the pancreas, and the superior surface

Fig. 1.



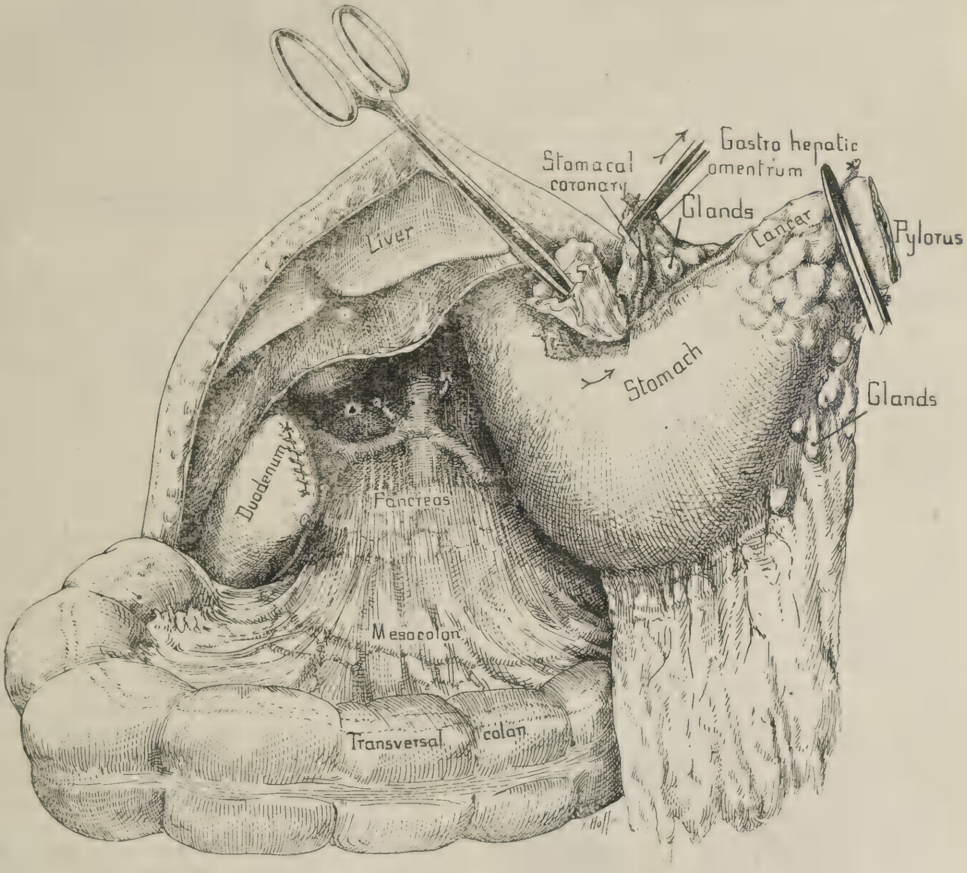
The illustrations were prepared in France.

The lesser sac has been opened through the omental colic separation to explore the posterior surface of the stomach and duodenum. The great omentum is thrown upwards, and its avascular attachment to the anterior surface of the colon has been freed by a knife; this dissection was begun as far as possible towards the left. The posterior relations of the stomach are fully displayed. The tumour and glands are separated from the transverse mesocolon and pancreas; the pancreatico-duodenal artery is defined and ligatured. This stage is performed by gauze dissection, the director, or bistoury, includes also the freeing of the middle colic vessels in the transverse mesocolon and separation of the glands, all of which should remain attached to the stomach. Dotted lines on the pancreas show the situation of the glands removed.

of the transverse mesocolon in full view. The transverse colon is replaced in the abdomen and the transverse mesocolon, pushed down with it, carries the middle colic artery out of danger.

2. *Freeing of the stomach, the tumour, and glands.*[1]—As the omental colic separation continues the stomach is carefully detached from the pancreas, using the knife or a compress to strip upwards any glands now forming one mass with the stomach. The line of cleavage, having freed the stomach from the pancreas, is then prolonged well towards the right, separating the omental layer with care from the underlying transverse mesocolon as the duodenal region is reached. Here a director is passed under the stretched-out omental edge, leading the cleavage line under the serous attachment of the duodenum, which is thus mobilised, freed, and pushed upwards. During this last step the right gastro-epiploic artery and pancreatico-duodenal artery lying in the angle between the pancreas and duodenum can be secured. With the mobilisation of the serous layers over the duodenum the peripyloric and duodeno-pancreatic glands are freed, and carried upwards towards the block of tissues formed by the stomach and tumour, which is grasped in the operator's left hand. Still using the director and knife, the already cleared space on the antero-external aspect of the duodenum is continued round posteriorly, the intestine being cleared as "if it were an artery."

FIG. 2.



Clearing the lesser curvature of its glands. The coronary artery has been ligatured and divided by a knife between the ligature and a Kocher's forceps which draws the vascular pedicle towards the left. The remainder of the gastro-hepatic omentum is divided by a knife, and the incision passes on to the muscular coat of the stomach. The lesser curvature is cleared by gauze.

3. *Section of the duodenum and ligature of the coronary artery.*—The denuded duodenum, grasped in a crushing clamp and divided, is closed by a parallel suture whose loops pass over the clamp. Some extra sutures are placed over the first line, and an omental flap adds further security to the stump. The pyloric artery is ligated and the gastro-hepatic omentum divided as near the liver as possible. The stomach is then swung over to the left, and the assistant retracting the liver with a Doyen's retractor, the operator places the coronary ligature as near the origin of the vessel as possible.

4. *Clearing of the lesser curvature.*—Pauchet performs this important step by placing a Kocher's forceps on the coronary pedicle a short distance below the liga- forceps stretches upwards the part of gastro-hepatic ture. With a sharp knife he divides the arterial pedicle close to the forceps, the incision passing right on to the serous coat of the lesser curvature. Traction on the omentum still attached to the stomach with its contained glands. With the blade of the knife on the flat, by a gentle scraping movement from above downwards, the serous coat, vessels, and glands are detached from the lesser curvature, traction on the forceps aiding their separation. The stripping of the curvature ceases where it is decided to cut the stomach across.

5. *Removal of the stomach and gastro-enterostomy.*—A crushing clamp, de Martel's or Payr's, is placed across the stomach, and the diseased portion distal to the clamp is cut away by the thermo-cautery. A continuous linen suture, its loops passing over the clamp, is rapidly placed along the gastric section, the clamp is loosened, and the suture drawn tight in the same way as the duodenal suture, the stomach being thus closed by a purse-string suture. Probably some surgeons would hesitate to confide the gastric section to the infolding suture over the clamp, and would prefer doubly to suture the stomach after removal of the crushing clamp. Gastro-enterostomy is then performed on the posterior or anterior surface of the stomach with a short loop of jejunum brought up through the mesocolon. If the gastric stump is very small Pauchet sometimes employs the Murphy button for the anastomosis, or unites the jejunal loop laterally to the section of the stomach after the Polya method.

Advantages of Omental Colic Separation in Gastric Operations.

Pauchet holds that omental colic separation, the first stage of this procedure, should be systematically used in many gastric operations, as it simplifies them considerably. He sums up its advantages as follows.

---

[1] Traitement Chirurgical des Maladès de l'Estomac. Atlas de 50 pp. et 90 figures. 1919. Paris: Maloine éditeur, 25, rue de l'Ecole de Médecine. Par Victor Pauchet.

1. The recognition of ulcers or other lesions which may pass unnoticed in mere superficial examination.

2. The possibility of dissecting with the greatest precision ulcers and cancers adherent to the pancreas or transverse mesocolon.

3. In cases of cancer, the greater facility in freeing the chain of glands which lie along the terminal portion of the greater curvature, the lower aspect of the pylorus, and the first portion of the duodenum.

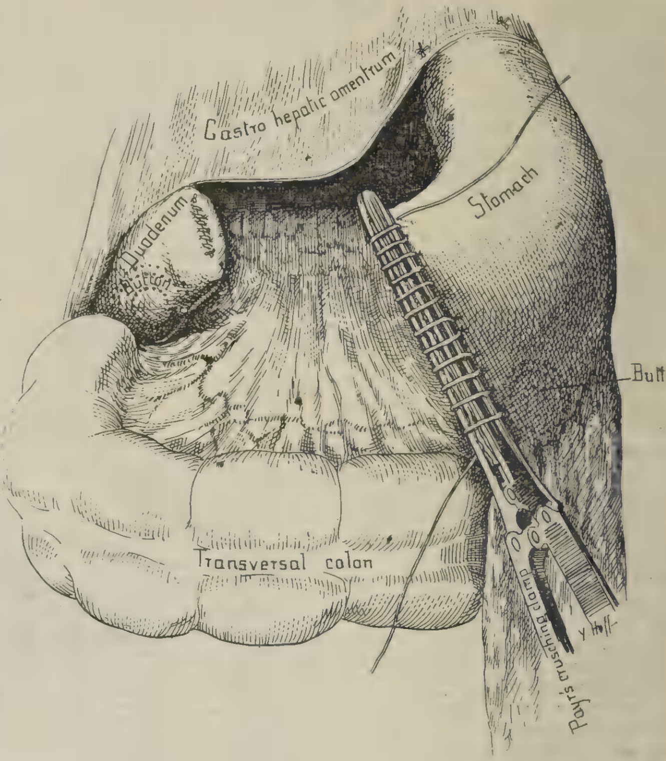
4. Further, in cases where the surgeon may decide definitely to resect the mesocolon if invaded also by the growth, the most simple and rapid method of removing the zone of the transverse colon irremediably deprived of its blood-supply by the ligature of the mesocolic vessels, is to extend the omental colic separation round the hepatic angle of the colon as in "mobilisation" of the colon, the usual procedure in removal of the cæcum and ascending colon.

The terminal ileum is then anastomosed to the transverse colon where its vascular supply is assured.

Gastrectomy performed by this method can be rapidly executed, and in cases of non-adherent pyloric tumours becomes a comparatively simple operation, due largely to clarity of anatomical detail. In our gastric work with Dr. W. A. Mackay we have proved the value of omental colic cleavage. In gastro-enterostomy the abolition of the loop revolutionised that operation, banishing the nightmare of the vicious circle; in gastrectomy this exsanguine proceeding has, more than any other factor, facilitated our resections both in malignant and benign disease.

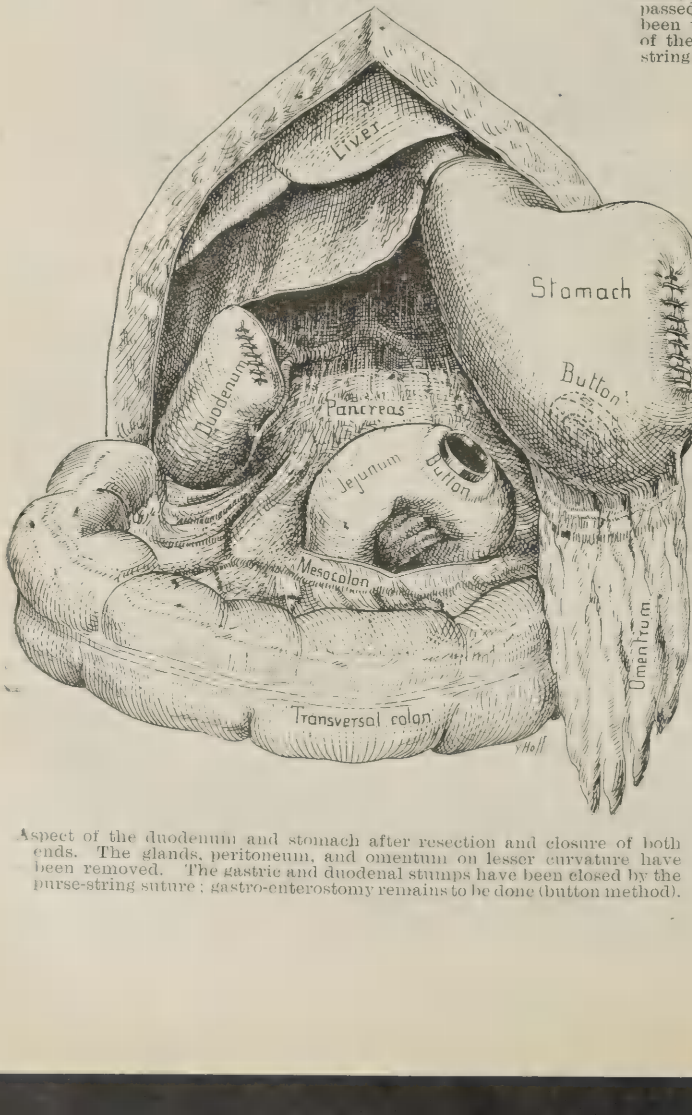
Huelva, Spain.

FIG. 3.



Closing the stumps of the duodenum and stomach. The stomach, grasped in a crushing clamp, has been divided along the clamp, over which a continuous suture is passed. The crushing clamp of the duodenum has been withdrawn; traction has been made on each end of the suture, and the duodenum is closed by a purse-string suture.

FIG. 4.



Aspect of the duodenum and stomach after resection and closure of both ends. The glands, peritoneum, and omentum on lesser curvature have been removed. The gastric and duodenal stumps have been closed by the purse-string suture; gastro-enterostomy remains to be done (button method).

BRISTOL AND THE ENDOWMENT OF RESEARCH.—The Committee of the University Colston Society, Bristol, is going to resume its custom of holding an annual dinner and of making a collection there for the benefit of the Colston Research Fund. Both dinner and collection fell into abeyance during the war, but it is to be hoped that the Fund will not merely come to life again, but that it will also reach a far higher figure than heretofore. So far it has never amounted to more than about £500—a useful beginning, but no more than a beginning. The President for the year is the Bishop of Bristol, the President-elect Alderman Frank Sheppard, a much-respected Labour leader. Bristol University is the only one with a fund of this character to stimulate its work, and the value of an incentive to research is considerable.

A CASE OF

HYDATID INFESTATION OF BONE, WITH MULTILOCULAR HYDATID DISEASE.[1]

BY C. E. CORLETTE, M.D., CH.M. SYD.,
SURGEON TO THE SYDNEY HOSPITAL.

Hydatid disease has not lost its interest for us in Australia. It still kills people. It still furnishes problems of many kinds. And we are still finding new matter for study, from which we can reach forward to some new knowledge, and by which we can test the value of current views. The case here recorded, I think, represents an instance of this.

H. H., male, aged 65, from the Coonamble district, New South Wales, was admitted to the Sydney Hospital on Nov. 2nd, 1918, complaining of pain in the right thigh and hip and a swelling of the same thigh, said to have existed for eight years. Eighteen years ago he had had pneumonia, but, with this exception, had apparently enjoyed ordinary health up to nine years ago, when a horse fell on the limb. It was said not to have been broken, but he had been lame ever since. Three years later he was run over by a cart, when the limb became very swollen. The swelling was incised at the time and had never entirely disappeared. The patient had walked with a stick for several years, and for the last five years had been subject to attacks of stabbing pain in the thigh and buttock. Twelve months ago he noticed the appearance of a small swelling in the groin, and three months later a larger swelling appeared below the inguinal ligament.

Present condition (Nov. 2nd).—Lies with right leg everted, and is unable to rotate it inwards. The right lower limb is 15 cm. shorter than the left. There is a large, uneven tumour, smooth in contour, most prominent above and internally, and projecting there about 2 or 3 cm. It extends downwards from the inguinal ligament in the femoral region to near the junction of the middle and lower third of the thigh. It is not tender on pressure, elastic, but not fluctuating. In the inguinal region is a further large swelling, which is soft and elastic to touch and gives an impulse (?) on coughing. The swelling fills up the inguinal canal and is reduced in size by pressure. Over the most prominent parts of the swelling the skin has a dusky red, congested appearance. Behind, a large, tense, elastic tumour can be felt below the gluteal fold. The muscle of the thigh is considerably wasted, and the upper portion of the thigh is disproportionately large as compared with the lower part. On palpation of the abdomen a large elastic mass can be felt outside the lateral border of the rectus, extending up from the inguinal ligament to the right costal margin. It is not tender except to a slight degree in the angle between the twelfth rib and the sacro-spinal muscle. The area of the mass is dull to percussion, and it is continuous with the liver dullness above.

The arteries are thickened, the heart sounds distant, and the second aortic sound accentuated. The only note about the respiratory system is that the patient suffers from a cough.

A radiographic examination was made, and the plate showed fracture of the right femur at its upper extremity, with appearance suggesting a new growth. There was great enlargement of the bone. The shadow of the ilium was faint and ill-defined and showed irregular defects of calcification.

Operation.

On Nov. 6th, under anæsthesia, a small incision was made over the upper of the two tumours in the region of the groin. Immediately a large quantity of a soft, mushy material, of granular consistency, and somewhat resembling boiled milk-sago, flowed out of the opening. A close naked-eye examination showed that it consisted of enormous numbers of minute hydatid cysts mixed with apparently granular material. (These granules were found later on to be more minute hydatid cysts, of microscopic dimensions.) The material, therefore, consisted of a pultaceous mass of closely packed hydatids. A finger was then inserted and a large cavity was discovered containing several sacculations, dividing it up into loculi. Somewhere on its mesial wall a small opening was found, at first not large enough to admit the finger. This opened out into another large sacculated cavity, extending downwards into the femoral region, and dipping deeply into the adductor side of the thigh, but subcutaneous in its anterior portion. Both these cavities contained also numerous small pieces of friable calcified deposit, one or two pieces being as large as the terminal phalanx of a finger. These pieces were obviously not bone. From beside the first cavity a small, separate sac, about as large as a walnut, was dissected out entire, and found to contain the same material as the cavities first opened. There was no trace of any mother-cyst. The cavities were washed out with saline solution, and the wound closed without drainage.

The wound looked well and matters went on all right for a week, but it gaped again, unhealed, when the sutures were removed. Immediately enormous quantities of the same soft, sago-like material began to pour out. The tense, elastic tumour behind disappeared and its site became soft and lax. The edges of the wound showed some redness, the temperature rose somewhat, though not very high. On the tenth day a few blood clots began to exude from the opening, and continued to escape till the patient died, on the twelfth day. The apparent hæmorrhage was not very large. The sago-like discharge continued to the last.

Post-mortem Examination.

The cavity opened up at the operation was found to intercommunicate with other larger and smaller loculi around the upper part of the femur, and these again with other cavities passing up behind the iliac bone and through erosion-holes and also via the obturator foramen into the pelvis and thence upwards. The swelling which had been noticed behind the hip, below the gluteal fold, belonged to a very large cavity extending up over the dorsum ilii. It was found at the post-mortem examination that this contained, together with the material which has been described, a large quantity of blood-clot. It seemed that the chief bleeding had occurred in this cavity, and that it might be explained by rupture of a large vein on relaxation of the hydrostatic pressure as the hydatid material drained away.

The large mass noted on the right side of the abdomen was found to have been produced by an enormous ramifying cavity reaching from within the pelvis up along the general course of the psoas as high as the liver, but not invading this organ or the kidney. The cavity was mesial in relation to the kidney and partially covered it.

Bone lesions.—As for the bone, the right side of the pelvis was eroded everywhere, and its skeletal structure was reduced to a fretwork, or network, of thin bone. The acetabular cup had vanished, and with it had vanished the head of the femur. (Fig. 1.) Through the perforation extended a large branch connecting the upper cavity with the cavity in the femur. The neck of the femur was tunnelled by this, so that only the cortical part survived. The tunnel opened into a large gap at the top of the shaft of the femur, the trochanteric part of the bone being very widely expanded around it. The cavity here became continuous with the loculi around the femur and the dorsal surface of the ilium. The congeries of intercommunicating cavities from above the kidney down into the upper part of the thigh, notwithstanding all the drainage that had been going on, still contained several pints, perhaps several quarts, of the characteristic, creamy-white, mushy agglomeration of tiny hydatids that had oozed out at the operation. But they were not all so small. There were larger cysts, though few in number, measuring up to 2 cm. in diameter.

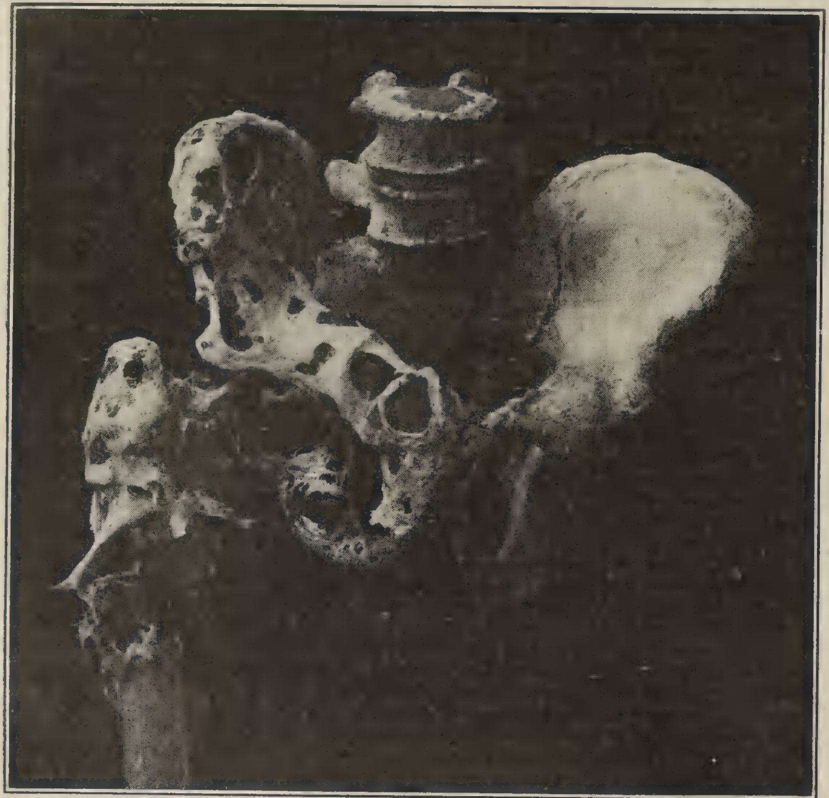
In addition to the system of intercommunicating cavities on the right side, other separately encapsuled accumulations of the same material were discovered at the post-mortem examination. One was a very large sac lying in the soft parts of the left thigh, mainly posterior. It reached from the level of the upper end of the bone above nearly to the popliteal space below. Another was a sac between the spleen and the diaphragm, the top of the spleen forming its floor, and the under surface of the diaphragm forming its roof. This accumulation was about the size of a small orange. It will be remembered that still another small separate sac was removed entire at the operation.

---

[1] This is an abridgement of an article which appears in full in the Australian Medical Journal.

Kidneys and liver.—The kidneys and liver were entirely free from any sort of hydatid growth or deposit. So was the left lung. But the right lung presented a very remarkable appearance. The whole of the apical part looked like marble, giving the impression that a series of small hydatid cysts were lodged beneath the pleural surface. At the lower margin of the upper lobe another hydatid mass could be seen, about the size of a pigeon's egg and elastic in consistency. This was incised and found to contain a densely packed mass of crumpled-looking hydatid membrane, cutting like a solid jelly. No free fluid exuded from the section, and there was no sign of an enveloping mother-cyst. No further cut was made in the fresh tissue, but it was put into hardening fluid for examination later on. As it turned out, this was a pity, for it spoiled the prospects of a good photograph. There were no pleural adhesions.

FIG. 1.



Hydatid infestation of bone, showing the right os innominatum and the upper end of the right femur expanded in the form of a thin bony network.

Lung.—The hardened lung was sliced up on Feb. 3rd, 1919, and an extremely interesting condition presented itself—no less than a multilocular hydatid of the lung. (Figs. 2 and 3.) The marbled appearance seen at the apex was not due to separately embedded hydatid cysts, but to digitations of an infiltrating mass of crumpled hydatid tissue. At the apex the mass was distinctly more cystic and less solid than at the lower aspect of the lobe, and there were larger cystic formations, but all irregular and crumpled. Separate cysts could not be isolated from one another, but there were a few isolated small-sized cysts lying outside the main mass and enveloped by normal-looking lung tissue. There was distinct mineralisation of a few of these outpost cysts, none of which was larger than grains of wheat, but all quite as hard. It could not be said that the main mass was appreciably calcified. The main mass extended through the lobe from its lower surface up into the apical portion. Serial cuts showed its continuity, though in the middle part it showed less prominently and seemed to be more mixed up in the connective tissue framework of the lung. It might be said that the whole existed as a somewhat sinuous formation of densely packed hydatid substance, about the thickness of a finger in its middle and expanding towards the apex and base of the lobe. The apical part was digitated, not, however, by connective tissue framework, in such a way that it might be compared roughly to the contour of a moderately distended kidney pelvis.

The brain, unfortunately, was not examined.

The vertebral column in the lumbar region was sawn through, and the part below was removed with the pelvis and femur for maceration and preparation as a museum specimen. The bony fretwork which represented the right side of the pelvis was so delicate and attenuated that, in spite of every possible care, some breakages occurred.

The prepared specimen is shown in the excellent photograph. (Fig. 1.)

Microscopic Examination.

I made a microscopic examination of the sago-like material from the bone cavities, &c. In the first place there was a large quantity of granular debris. The tiny grains, down to dimensions smaller than were distinguishable by the naked eye, were seen to consist of small hydatid cysts with the characteristic striated cuticle. Some of the larger cysts were also examined in the same way. In no case were any scolices or hooklets detected.

Microscopic examination of sections of the lung lesion showed that the whole tract was infiltrated with hydatid material. The hydatid membrane had fallen away from the adventitious investiture in most cases, leaving gaps in some of which shrivelled masses of hydatid membrane could be seen. The largest lacunæ of this sort were in the apical portion. In the intermediate portion the cysts were grouped in numbers of small masses close together. Here they were mostly of very minute size, much smaller than could be separately distinguished by the naked eye. Fine fibrous trabeculæ separated the groups into loculi. Many of these trabeculæ had been cut by the section knife. The normal tissue of the lung lay adjacent to these infiltrating masses of tiny hydatids without any very remarkable walling off. Around the apical masses small-cell infiltration was more noticeable, but in the intermediate part there was neither excessive development of fibrous investiture nor other evidence of great reaction. There was certainly nothing to give confirmatory evidence of the violent tissue reaction which Melnikow-Raswedenkow[1] has described. Neither scolices nor hooklets were discovered.

Remarks.

The case is of special interest because of the unusual combination of lesions in bone and in soft

tissues. One of the arguments against the theory that cystic and multilocular hydatid disease are caused by the same parasite is the comparatively small size of the cysts in the latter. Virchow[2] suggests that the limitation of free growth by the pressure of Glisson's capsule, or of bone, might account for this difference in size. This suggestion would not apply to my case, where the cysts were small, even in soft tissues, but since they were frail and delicate, rupturing at the slightest violence, the churning up of the mass as the patient moved would certainly account for the bursting of the larger ones. Moreover, with such a prodigious number of individuals massed together in the closest contiguity there would also be nutritional difficulties, and the limitation of food-supply would interfere with growth. It is probably a similar cause that keeps the daughter cysts within an ordinary hydatid small.

Again, according to Davies Thomas,[3] the channel adopted by the hydatid embryo from the portal system to the bone is probably that of an embolus through the heart into the systemic circulation. However, another method of hydatisation (if I may coin such a word) is the infection of the peritoneal cavity by rupture of a fertile cyst into it. I have on one occasion removed a small hydatid cyst from the subcutaneous tissue of the abdominal wall. It is conceivable that the rupture of such a cyst, if fertile, might cause liberation of scolices, some of which would enter the general circulation through the venous channels, though most of them would probably enter lymphatics. The analogy of fat embolism (Caldwell and Huber[4]) should be remembered in this connexion. I consider

FIG. 2.

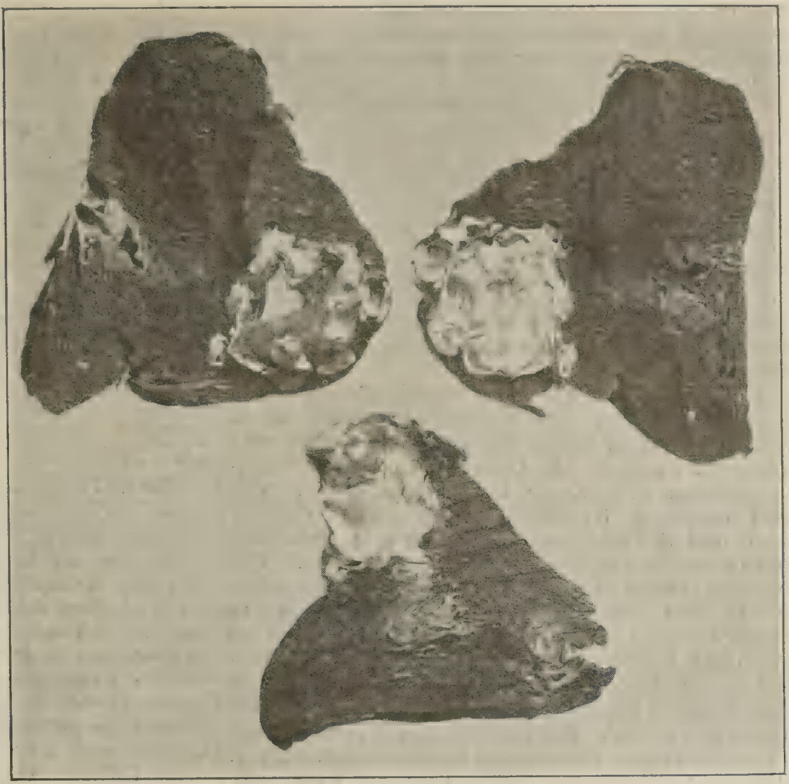


FIG. 3.

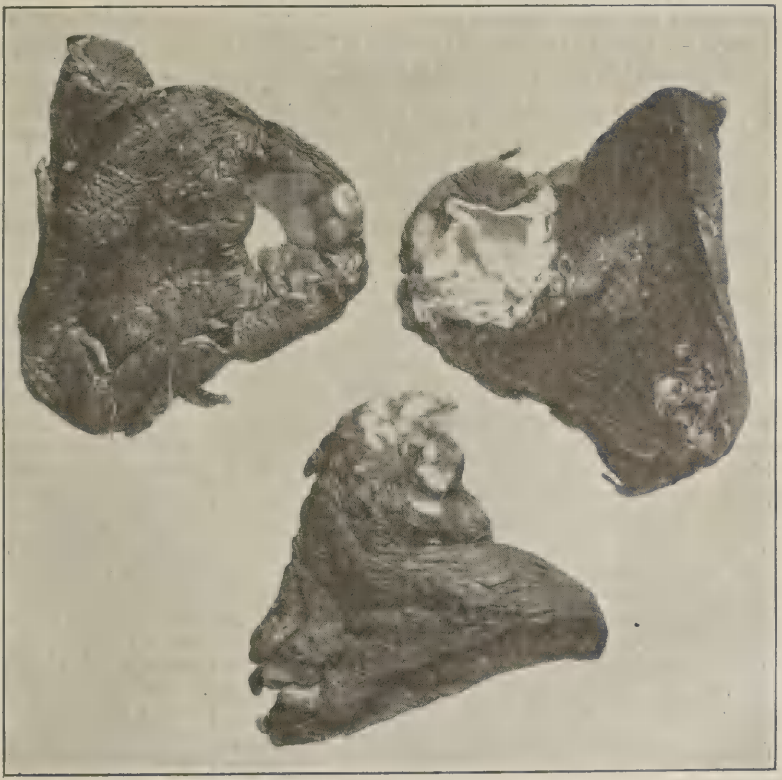

FIGS. 2 and 3.—Multilocular hydatid of lung.

The figures are from photographs of a series of sections of upper lobe of right lung of H. H. In each figure the apex of the lung is directed towards the centre. Observe the appearance of the anterior aspect of the apex (in the holed specimen), where a crowded mass of hydatids was bunched so as to give a marbled appearance to the fresh specimen. An examination of the sections will show how the infiltrating mass of hydatid material traces an irregular sinuous course through the substance of the lung to the base of the lobe, where it expands to form a larger mass of crumpled up and tightly packed hydatid material. Most of the infiltrating mass consists of closely set cysts of minute size, set in an irregular connective tissue stroma, and in close relation to normal lung. The rest of the lung shows a few spots indicating small outlying cysts, but is otherwise healthy.

that in my case the bone lesions, which had given rise to symptoms of many years' duration, were likely to have been present before the lung lesions, and that in the latter we have an embolic multiple metastasis reaching the lung through the blood stream.

If medullary fat can enter the circulation when vessels are torn and kept unsealed, so might minute embryonic components of the parasitic mass, and possibly even tiny cysts, gain entrance to the venous current and be carried to the lung in a swarm. A very close seeding of a portion of lung with embolised embryonic hydatids or tiny cysts would presumably be enough to create an agglomeration answering the description of a multilocular hydatid; this hypothesis could probably be tested experimentally by intravenous injections into animals.

As to Melnikow-Raswedenkow's[1] theory of a separate parasite, his biological work is so imaginative as to make me suspect that he may have seen some of his facts through the distorting medium of a ready forged hypothesis. The cases recorded by Stirling,[5] Poulton,[6] Watson,[7] Hahn, and Stirling and Verco[8] seem to link bone hydatid securely to the common cystic form. The condition found in the lung of my case, after taking into consideration the difference in the structure of the organs attacked, allows no reasonable doubt of its identification as a multilocular (or alveolar) hydatid formation strictly comparable to the descriptions of the same disease affecting the liver. But in the same person existed an equally typical example of bone hydatid. Thus, since each of these conditions is an extremely rare phenomenon, the identity of the parasite causing each lesion is practically demonstrated, and the inference may reasonably be drawn that multilocular hydatid disease of the liver is also produced by the same kind of parasite.

WAR ŒDEMA IN TURKISH PRISONERS OF WAR.

BY J. I. ENRIGHT, M.B., B.A. N.U.I.,
CAPTAIN, R.A.M.C.

IN the autumn of 1916 I became attached to No. 2 Prisoners of War Hospital, Cairo. As I had been resident only a few months in the East my knowledge of tropical medicine was very slight; and on taking up duties at this hospital I was immediately confronted by clinical manifestions of diseases previously unknown to me.

Dr. A. D. Bigland[1] had made a careful study of the œdema cases occurring in No. 2 Prisoners of War Hospital, Cairo, up to July, 1917, when he was unfortunately compelled to relinquish his work. From that period onward I took up the threads and continued his work.

I propose to give a short summary of the principal features observed in connexion with 54 cases out of some 300 that came under my notice, dwelling particularly on the character and distribution of the œdema. The general condition of all the patients was bad. They were weak and emaciated. Some were so feeble as to be unable to sit up in bed without assistance. There was marked pallor, and diarrhœa was invariably present. They showed a general disinclination for food, and, in fact, seemed to have lost all power of assimilation, as evidenced by the presence of undigested food material frequently seen in their stools.

I shall not attempt to give an accurate account of their previous history, as the majority of them were so vague in their replies that little credence could be placed in their answers. However, a good inference as to what diseases they had had can be gained from a scrutiny of the diseases concurrently present as shown in the table.

Total number of cases 54

Pellagra	47	Pulmonary tuberculosis ...	1
Dysentery	27	Pellagra and dysentery... ...	24
Malaria	15	Pellagra and pulmonary tuberculosis	1
Diarrhœa	19		

Thus, it is seen that the most commonly associated malady is pellagra, which is present in a large majority of the cases; whilst if we regard dysentery as being elementarily diarrhœa and include its occurrence under the head of the latter, we find that diarrhœa also occurs in very many cases. The malaria incidence was probably much higher than as shown in the table. As the diagnosis of the condition was based principally on the presence of a large spleen, which could not always be palpated with certainty, especially when ascites was well developed, malaria was in all probability overlooked in many cases.

Hence we may surmise that pellagra, dysentery, and malaria were the most commonly occurring antecedents of this extraordinary œdema, and presumably filled an important rôle in its ætiology, which shall be discussed later.

Distribution and Character of the Œdema.

The mode of onset varied. Usually it was gradual, first manifesting itself as œdema of the feet and afterwards slowly spreading to other parts until it finally terminated in general anasarca. More rarely, cases of massive and generalised œdema were seen to supervene comparatively suddenly. Two such cases occurred in a few days. The œdema was progressive. Despite rest in bed and appropriate dietary it continued, and was apparently in no way influenced by treatment. As previously noted, frequent tapping of the cavities was necessary, as there was a great tendency to fresh formation of fluid. I remember one patient whose pleural cavities and abdomen required aspiration weekly. He had severe abdominal pain and dyspnœa, which were usually relieved by withdrawal of the fluid.

However, even though many cases resulted in general anasarca, exhibiting huge œdema of the lower limbs with marked pitting, ascites, pleural effusion, œdema of scrotum and penis, and swelling of the face and entire back, others had the œdema more or less circumscribed. That is to say, the condition began and remained as œdema of the feet alone or as an ascites. A common combination was that of the face and lower limbs. In most cases swelling of the uvula was noted, whilst two cases had superficial œdema of the abdominal wall.

A point of great interest was the appearance in a few of a discrete subcuticular hæmorrhagic rash in association with œdema of the legs, which were rather indurated and painful. Evidently a scorbutic factor was involved in these.

---

[1] Dr. A. Douglas Bigland's paper, entitled "Œdema as a Symptom in So-called Food-deficiency Diseases," appeared in THE LANCET, Jan. 31st, 1920 (p. 243).

General Symptoms.

The patient complained of marked debility, and in the advanced stages of the illness became so weak that he could not attend to his needs. Diarrhœa, frequently turning into dysentery, was almost universally present, and proved most intractable. The temperature was only slightly elevated, except in cases complicated by pulmonary tuberculosis, when, of course, it was much higher than normal. There were some cases which had no pyrexia. Pyorrhœa and spongy, congested gums were also observed, and it may be mentioned that night-blindness, without any apparent ocular changes accompanying it, was by no means uncommon. Dr. H. P. Keatinge, late director of Kasr-el-Aini Medical School, Cairo, found an extraordinary prevalence of night-blindness amongst the native troops engaged in Kitchener's Sudan campaign. He attributed it to scurvy, which was then rampant. There were no characteristic nerve changes. In some patients the knee-jerks were very sluggish, almost absent, whilst the cornea and pharynx were often found to be insensitive. However, the pronounced asthenia was probably sufficient to explain this alteration in nerve response.

Physical Signs.

As a rule the heart showed no signs of organic disease. Occasionally a bruit of hæmic origin was heard. Generally the heart sounds were weak and the pulse was rapid and lacking in volume. This latter fact is important, inasmuch as most continental observers associate bradycardia with their cases of war œdema. Only 2 out of the 54 cases exhibited dilatation which would account for the dropsical condition. Hence, in the vast majority the œdema could not be ascribed to cardiac incompetency, and its causation, therefore, must be sought elsewhere.

No obvious lesions in the lungs were detected excepting in those cases which had pulmonary tuberculosis. As previously stated, pleural effusions were common, and when fluid did not occur the lungs were usually normal.

In cases complicated by malaria the spleen was enlarged and hard; otherwise it was not palpable.

Urine: Albumin was almost invariably present. Sometimes it was represented by a trace; frequently the urine was loaded with it. Much less often albumin was absent and the urine was perfectly normal. There were two cases of general anasarca in which the urine was absolutely normal. A few cases had casts, pus, and a large quantity of albumin. In these latter definite degenerative changes of the kidney had arisen, and probably accounted for the œdema. But the largest proportion showed nothing abnormal excepting some albumin. Consequently the kidney cannot be accused of being instrumental in the production of the œdema.

There was no frequency of micturition. The average daily urine content varied from 45–55 oz. Even under the influence of diuretic treatment no marked diuresis occurred. This failure to promote an increased urinary flow rendered the œdema more persistent, and seriously vitiated the prospects of a hopeful prognosis.

Blood: The blood usually showed an anæmia of the secondary type. There was an absolute diminution in both the red and white blood cells. A characteristic blood count was—

Red blood cells	3,500,000	Polymorphs	36
White blood cells... ...	4,000	Lymphocytes	48
Hæmoglobin	60	Mononuclears	16

In many cases a relative lymphocytosis occurred, whilst the frequently occurring mononuclear increase was evidence of malarial infection. No variation from the normal in the eosinophils was observed. The blood pressure was very commonly lowered, the average systolic pressure being about 100, the average diastolic being about 85.

Post-mortem Changes.

There was a marked absence of subcutaneous fat. All the organs were found to be abnormally reduced in size and weight. The heart, lungs, liver, spleen, and kidneys were similarly affected. The heart usually weighed only 3–5 oz., but in other respects was apparently normal. The liver was almost constantly the seat of fatty degenerative changes. In the malaria-complicated cases, the spleen was enlarged, hard, and pigmented, but in the non-complicated the spleen was very small, sometimes weighing only 3 oz. and of normal consistency. When pulmonary tuberculosis did not accompany the œdema the lungs were normal. The kidneys and suprarenals were shrunken in size, but were otherwise normal. On one occasion a hæmorrhage into a suprarenal was noted. Evidences of dysenteric ulceration—either old or recent—were almost constantly present in the descending colon and rectum. The ulceration was chiefly of the bacillary form.

Owing to absence of facilities the histological changes in the various organs could not be investigated.

Factors in Causation.

As to what factors are operable in the production of the œdema I cannot yet state accurately. An analysis of the concomitant diseases is instructive and may probably help to shed some light on the causation. The incidence of pellagra is remarkably high. Dysentery and malaria, though occurring in much less proportions, are frequently present.

It would seem that this œdema and pellagra are in some extraordinary manner associated, and it is quite rational to suggest that the origin of the œdema is due to the same elements that are responsible for the causation of the pellagra. As the ætiology of pellagra is by no means definitely established this suggestion does not elucidate the matter much further. I may add that I am reserving for another occasion a treatise on the results of my observations of a number of pellagra cases which were under my care for an extensive period. I shall then have an opportunity of discussing its causation, as I am in a position to give a detailed account of the previous diets of the patients.

At this juncture it is sufficient to say that my conceptions of this œdema are that it is due to a combination of two factors—food deficiency and debilitating diseases—e.g., malaria, dysentery, pulmonary tuberculosis, &c.—operating to produce a third factor—adrenal insufficiency—which is the immediate cause of the condition. Whether the food deficiency chronologically precedes the onset of the debilitating disease or vice versa can be only conjectural. I personally think that the debilitating disease or diseases occur first and thus render the system more receptive of the deleterious influences that accrue from the subsequent food deficiency.

Malaria, dysentery, tubercle, &c., were extraordinarily prevalent among the Turkish forces in Palestine, whilst their food-supply during the last 12 months of the campaign was in a precarious condition. That something more than the dietetic element was involved is obvious from the failure of response to treatment, which was almost universal in these œdema cases. In beri-beri, scurvy, and other dietetic diseases the prognosis is distinctly good when the missing food factor is restored. These cases, however, did not respond to improved food conditions, and thus it may be assumed that this peculiar œdema, though closely allied to the food-deficiency diseases, is a distinct entity. That a dietetic agency is engaged is evident from the following observations made in this epidemic: (1) The remarkable similarity of some cases to wet beri-beri. (2) The frequent coexistence of scorbutic symptoms—e.g., spongy congested gums, brawny swelling of the legs accompanied by a subcuticular hæmorrhagic rash, and night-blindness. (3) The close parallel existing between the physical signs and symptoms recorded and the results obtained by McCarrison in his experimentally fed pigeons. He noted in pigeons fed on a diet deprived of certain accessory food factors a high incidence of œdema, great wasting, marked derangement of gastro-intestinal digestion, malnutrition of the nervous system, a secondary anæmia of the red and white cells of the blood, and pronounced atrophy of all the organs, excepting the suprarenals, post mortem. Strange to say, the suprarenal glands of the pigeons were always enlarged, whereas the suprarenals of all our Turkish prisoners were found to be atrophied. As previously observed, a hæmorrhage into the suprarenals was discovered in one prisoner.

McCarrison attributes the œdema in his pigeons to hyperadrenalinæmia, causing increased intracapillary pressure and acting in concert with malnutrition of the tissues.

Malaria also exerts a very important influence in the production of the œdema. Already in a paper which has been accepted for publication in the *War Office Malaria Journal* I have drawn attention to the development of ascites and œdema even in early cases of malaria. These cases I described as examples of so-called malarial nephritis, as they closely simulated true nephritis. The urine, however, although frequently showing albumin, never contained casts. They responded to antimalarial treatment, with the rapid subsidence of the ascites and œdema. No local focus could be found to explain the origin of the œdema, which was ascribed to the direct action of the malaria parasite or its toxins.

The researches of Paisseau and Lemaire[2] at Salonika are of still greater interest, as they proffer an explanation of the œdema in malaria. Some of their malignant malaria cases manifested a condition of hydræmic cachexia, consisting of anæmia, œdema, and profound asthenia. This phenomenon occurred during the course of even a primary infection, and the mortality was very high. In patients who had succumbed to this variety of malaria they found very important lesions, sometimes degenerative, sometimes hæmorrhagic, of the adrenal capsules, which showed a great accumulation of hæmatozoa. They accordingly attributed the condition to adrenal insufficiency.

Hence it is established that malaria plays an important rôle in the causation of œdema.

The part played by dysentery is more obscure. That it is in some way implicated is evidenced by the frequency with which dysenteric ulceration has been noticed in the intestines in these cases. It is obvious that intestines infected by dysentery cannot undertake their normal functions as regards digestion and assimilation. Thus even mechanically dysentery may be regarded as aiding and abetting in the food-deficiency factor. In a previous contribution I described[3] a peculiar septicæmia occurring rather frequently in Turkish prisoners of war. I attributed it to infection from the lower bowel, as practically all the cases had a history of previous dysentery. On reading McCarrison's[1] "Pathogenesis of Food Deficiency," I was struck by the fact that there was a high incidence of septicæmic infections in his experimentally fed pigeons. He thought the septicæmia was due to some toxic influences under conditions of food deficiency. These pigeons also developed œdema. In the case of the septicæmia amongst the Turkish prisoners the dysentery was the toxic influence whilst a dietetic factor was involved too. It is quite probable that if these cases of septicæmia had been more advanced, œdema would eventually have arisen.

Thus, although no definite date can be adduced to prove the exact effect of dysentery in the production of œdema, it is quite feasible to consider it as a very useful adjuvant in its causation.

In conclusion, I wish to take the opportunity of thanking Lieutenant-Colonel P. S. Vickerman, late O.C. No. 2 P. of W. Hospital, Cairo, for his extreme kindness and help in this work.

ACUTE GLANDERS IN MAN.

BY T. HUNTER, M.A., B.SC., M.D. GLASG.,
LIEUTENANT-COLONEL, I.M.S; CIVIL SURGEON, NAINI TAL.

AS acute glanders in man is an unusual condition and one likely to give trouble in diagnosis, at least in its earlier stages, it has been thought worth while to put this case on record. The symptoms corresponded fairly closely to those described by Goodall in his text-book on fevers. This book, however, was not available for reference till after the termination of the case, and the only descriptions of glanders in man that could be found whilst the patient was alive were records of a much less acute infection, also in an officer of the Indian Civil Veterinary Department, described by himself.[1] That infection lasted two years and four months, and then, after an interval of eight months, lighted up again and lasted for a second period of two years. My case was totally different from this and its history is as follows:—

A veterinary officer aged 34 years, employed in laboratory work, was admitted to the Ramsay Hospital, Naini Tal, on June 22nd, 1919, complaining of fever, headache, pain in both legs and in the left shoulder, of six days' duration, the illness having definitely begun on the afternoon of June 17th with malaise, fever, and headache. The patient was a robust man. He had been inoculated for the enteric group in 1917. On admission the mouth temperature was 102° F. and the pulse 88 per minute, the tongue was heavily coated, and yet the patient did not look very ill. The pain complained of in the left shoulder seemed to be around rather than in the joint, but nothing abnormal could be found. On both calves there was an appearance like a small boil which had missed coming to a head; on the front of the left shin there was a red inflamed area like erythema nodosum, and on the dorsum of the left foot there was a painful area. Nothing abnormal was found in the chest or abdomen; the liver and spleen were not enlarged. A blood film showed distinct increase in the polymorph leucocytes. There was no sign of malaria.

The complaint of headache, the dissociation between temperature and pulse, and the appearance of the tongue, suggested a tentative diagnosis of one of the typhoid group. The increase in the polymorphs was definitely opposed to this, but it was conceived as possible that there was in addition to the typhoid an infection with staphylococcus causing the boils and accounting for the blood picture. Asked on the point the patient was definite that he had not been working with staphylococcus or other pyogenic organism.

---

[1] Journal of Comparative Pathology and Therapeutics, vol. xxvi. p. 223, and vol. xxix., p. 26.

Directly on admission blood was drawn from a vein and inoculated into oxbile; a Widal was also done. The report on these was that the blood in oxbile had remained sterile, but that the Widal gave a positive reaction to *B. typhosus* in a dilution of 1/500 and a feebly positive reaction to *B. paratyphoid A* in 1/50, and *B. paratyphoid B* in 1/100, and strongly suggested a typhoid infection. This confirmed the diagnosis arrived at clinically.

For the next week the temperature ran about 104°, generally below, occasionally above, and no new symptom developed. There was still the marked dissociation between the temperature and the pulse, the latter ranging between 80 and 100. But clinically the patient did not resemble a case of typhoid and doubts began to be felt about the diagnosis. A blood film taken on the 29th still showed marked increase of leucocytes. The boils were subsiding and the inflammation over the shin and foot was very much less. The following day the abdomen was slightly tympanitic, reviving the typhoid diagnosis.

On June 30th one or two small pustules appeared on the trunk and scalp, and the back of the right hand became inflamed. The bacteriologist took smears and made cultures from the pustules and reported them sterile. Blood was also taken and injected into broth, and again nothing could be grown.

Problems of Diagnosis.

It was now beginning to be perceived with certainty that the disease was either not typhoid or was typhoid with some other infection superimposed. In view of the profession of the patient, and as he had been employed in the manufacture of mallein, glanders was considered; but the sterile pustules seemed to negative this, and as the pustules were in some places umbilicated for a couple of days, the suspicion of small-pox superimposed on typhoid had considerable attention. On July 2nd and 3rd very many fresh pustules appeared and large confluent pustular areas were formed, worse on the scalp. In spite of the negative bacteriological reports a definite diagnosis of acute glanders was made on July 3rd. On the 4th it was manifest that the old inflamed area of the left shin had broken down, and there was a second area above the left knee which looked suspicious. An incision was made into each and from each a small quantity of thick gelatinous pus was evacuated. Some of this pus was examined bacteriologically and was reported to show practically pure cultures of a bacillus morphologically identical with *B. mallei*.

From this date the condition rapidly went from bad to worse. Fresh pustules continued to appear until it was hardly possible to find a piece of skin free for the area of a finger. Many coalesced and formed large pustular areas. The face was affected with the rest of the body, and the resulting swelling of nose and eyelids made the patient unrecognisable by his friends. From the evening of July 4th the patient was unconscious and breathing stertorously, though nothing was found in his chest at this stage. On the 5th abscesses were opened on the back of both hands and on the dorsum of the left foot showing the same thick gelatinous pus in very small amount. On the 6th examination showed coarse râles at the base of both lungs, doubtless hypostatic. Death occurred at 4 P.M. on this date.

Treatment was symptomatic and as for typhoid till July 1st, when intravenous injections of eusol, 100 c.cm. doses, were begun. These were given daily till the end. At first the pustules were opened, cleaned, and treated with tinct. iodine. They became so very numerous that this was discontinued on July 4th. The organism isolated from the pus was injected into a guinea-pig and produced typical orchitis of glanders as found in those animals, with an exudate into the tunica vaginalis from which bacilli like that of glanders were easily recovered.

The bacteriological investigations were conducted by Major A. Hayes, R.A.M.C., of the Naini Tal enteric depôt laboratory.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

AN OPERATION UNDER DIFFICULTIES.

By NATHANIEL CRICHLOW, M.B., CH.B. GLASG.,
GOVERNMENT MEDICAL OFFICER, BRITISH SOLOMON ISLANDS.

THE natives of the British Solomon Islands have been so accustomed to live amidst dirt, filth, and squalor that they seem to become immune to septic germs. I attribute the recovery of the following case to such immunity.

One morning I received a letter from the Father in charge of the Roman Catholic mission informing me that during the night one native stabbed another native in the abdomen and that the stomach and intestines were protruding through the abdominal wound. Although at the time suffering from an attack of malarial fever, I went immediately to the mission station. I examined the native and found that he had an abdominal wound 3 in. long in the epigastric region and running in an oblique direction. The cartilages of the sixth and seventh ribs were completely cut through. Through this wound protruded the stomach. The stomach itself had a wound $1\frac{1}{2}$ in. long and penetrating the entire anterior wall. Through this opening the contents of the stomach were oozing. The patient was in a collapsed condition and his pulse was very soft. Ten hours had elapsed between the time he was stabbed and the time I saw him. As the patient was not in a condition to stand a trip by water and as the hospital was some distance away I decided to operate on the spot. Unfortunately I had no instruments with me. I asked the Father what instruments, dressings, &c., he could supply and he informed me that he could supply me with the following: One pair of scissors, skin suture needles, catgut, rubber drainage-tube, wool, lint, lysol, chloroform. I decided to operate with these instruments, with the addition of my pocket-knife. The patient was lying in a native hut built of leaves and on a wooden bunk. The hut and the bunk were far from being clean.

Operation.—I washed the protruded stomach well with weak lysol solution and salt solution, then without any anæsthetic I stitched up the wound in the stomach, using the skin needles and catgut. Owing to the sharp cutting edges of the needles, great care had to be exercised in stitching up the stomach. The patient was then placed under chloroform. The abdominal wound had to be enlarged, and this I did with my pocket-knife. I then pushed back the stomach into the abdomen, covered it with omentum, inserted a drainage-tube, and stitched up the abdominal wound. Before I left I instructed the Father as to the care of the patient, the diet he should receive, and as to the dressing of the wound.

The following day I returned and fully expected to hear of the patient's death. Much to my surprise, I was informed that he was alive and apparently much better. I did, indeed, find the patient much better. His pulse was beating fairly strongly, there was very little abdominal pain, and he was able to converse with me. Four days after I again visited the mission station and was informed, to my surprise, that the patient was walking about. I dressed the wound and gave him 1 oz. of castor oil. I left in the drainage-tube for a week and then removed it. A fortnight later the abdominal wound had quite healed and the patient was walking about and eating anything he liked. He informed me he could eat just as well as before and had no epigastric pain.

This patient was operated upon in a dirty leaf house and on a dirty wooden bunk. Proper aseptic precautions could not be taken. A pocket-knife, a

pair of scissors, skin suture needles, and catgut were the only instruments used in the operation. I had to be anæsthetist as well as operator. The patient had very little skilled attention after his operation, except that his wound was dressed daily by the mission Father. Yet in spite of all these disadvantages three weeks after being stabbed he was walking about as well as ever, and was none the worse for his experience.

FOUR UNUSUAL CASES OF INTESTINAL OBSTRUCTION.

BY ALAN C. PERRY, M.R.C.S., L.R.C.P.,
LATE HOUSE SURGEON, LONDON HOSPITAL.

THE four cases described below, admitted to the London Hospital within a period of 48 hours, are recorded as being of general interest.

(1) *Atresia of the Small Intestine.*

M. S., aged 18 hours, admitted on Oct. 18th, 1919. Normal labour. Since birth had vomited continuously green froth and had not passed meconium. On admission well-developed child, vomiting greenish fluid. The abdomen was distended. About 1½ inches from the anus was felt what appeared to be an obstruction to the finger. No bulging downwards could be detected. A rubber catheter was passed and was obstructed at the same spot.

Operation.—A muscle-splitting incision was made in the left iliac fossa; the small gut was distended and ended blindly. This blind end was brought out of the wound and enterostomy performed with a small Paul's tube. The child never rallied and died about six hours later.

Post-mortem report.—Paul's tube in apparently blind extremity of distended upper 95 cm. of small intestine (7 cm. circumference). Proximal 30 cm. of distal segment of small intestine (0·7–1 cm. circumference) free from the main mesentery, greatly twisted upon itself, and bound by several band-like adhesions to the lower surface of the proximal intestine, to the sigmoid colon, and to the transverse colon. The omentum replaced by adherent bands. Notch (10 cm. long), with rounded border in mesentery, between the upper extremity of small gut and the base of the apparently blindly ending proximal 30 cm. of the distal segment. Upper segment distended with gas. Pasty greenish-black occasionally white content in lower segment. Pale greenish pasty substance in colon. No abnormality in rectum and anus. Almost complete collapse of both lower lobes of the lungs. Patches of collapse in posterior parts of both upper lobes. Ductus arteriosus and ductus venosus patent. Foramen ovale patent. Bile-stained mucus in stomach. Uratic casts in kidneys. Centre of ossification in lower end of femur. Great congestion of lips and nails. Well-developed male baby.

(2) *Acute Obstruction by Band Simulating Appendicitis.*

D. C., aged 4, admitted on Oct. 19th, 1919. This child was brought to the hospital, having been ill for 48 hours. She complained of gradual onset of pain in the right iliac fossa, where it had remained localised, incessant vomiting, and constipation. On admission the child looked very ill and her eyes were sunken. Her skin showed loss of elasticity. Tongue was dry and coated. Temperature was 99° F. and pulse was 136. The abdomen was slightly full, and the movement on respiration was markedly impaired in the lower abdomen. There were rigidity and tenderness over all the lower abdomen, but this was more marked in the right iliac fossa. On rectal examination no bulging of the pouch of Douglas could be felt.

Operation.—Under the anæsthetic an indefinite mass was felt in the right iliac fossa. A muscle-splitting incision over the mass was made, and later enlarged upwards. The small intestine was distended, and there was a considerable quantity of blood-stained fluid in the peritoneal cavity. The mesentery was studded with tuberculous glands, and there were numerous adhesions between the intestines. On tracing down the distended gut there was a sharp kink produced by a band attached to the mesentery and to the intestine near the mesenteric border. This band was divided. The intestine about 2 feet above was also joined to this point by adhesions and the portion in between was much discoloured, had lost its lustre, and did not contract. It was not considered viable, and about 2 feet of small intestine, extending to within 6 inches of the ileo-cæcal valve, was resected. End-to-end anastomosis was performed. A drainage-tube was passed to the pouch of Douglas after the abdomen had been irrigated with hot saline. After the operation patient's temperature continued to rise, and reached 105° before she died some 12 hours later. No autopsy was allowed.

(3) *Strangulated Sciatic Hernia with Pregnancy.*

C. P., aged 27, admitted Oct. 20th, 1919. Married, no children, no miscarriages; 18 weeks pregnant. Seven days before admission she had sudden acute pain in umbilical region, and vomited watery material. The attack subsided, and she was perfectly well in a few hours. Three days later she was seized with a similar acute pain in the umbilical region which radiated down the right leg and into the pelvis at times. The pain was colicky, and came on two to three times an hour. It was accompanied by persistent vomiting and much retching. The vomit was brownish in colour, but was not foul-smelling. Since this second attack of pain there had been absolute constipation. On admission: A well-nourished woman with anxious expression. Temperature normal. Pulse 112. Tongue dry and coated. The abdomen moved well with respiration, but was definitely distended, particularly in the hypogastric region. No visible peristalsis was seen. There was no rigidity or tenderness, except a slight degree over the lower part of the right rectus. The uterus could be felt reaching to within two inches of the umbilicus. No dullness was elicited in the flanks. On vaginal examination the os was patulous, but the fornices were very tender and difficult to examine. The pouch of Douglas appeared to be empty. On rectal examination a few hard scybalæ were felt which were washed out by two enemata. These were returned without relieving the obstruction.

Operation.—An incision was made in the mid-line below the umbilicus and the recti separated. The small intestine came into view and was markedly distended. A portion of collapsed gut was also found and the two were traced respectively downwards and upwards. They were found to meet in the right side of the pelvis where the intestine was firmly fixed. On attempting to bring up the obstruction to the wound the gut was inadvertently torn. About three inches of gut was then resected, including the tear, which was seen to have been through the constriction ring of a Richter's hernia. End-to-end anastomosis was performed. On examination of the pelvis there was found to be a hernial opening passing into the right sciatic notch above the pyriformis. The sac admitted the tips of two fingers for about half an inch, and in this the strangulation had taken place. A drainage-tube was passed into the pouch of Douglas and the wound closed in layers. The patient was nursed in the Fowler position. There was some difficulty in getting the bowels to act at first, but afterwards she made an uninterrupted recovery.

She was discharged on Nov. 19th. Her wound was well healed and her pregnancy undisturbed. The uterus reached to within one inch of the umbilicus. On vaginal examination the os was still somewhat patulous and there was still some tenderness in the right fornix, which bulged slightly.

(4) *Acute Obstruction by a Band in an Elderly Man.*

J. W., aged 56, admitted Oct. 20th, 1919. This man was admitted complaining of gradual onset of pain in the umbilical region of the abdomen for four days. The pain was not severe, but was dull and aching in character. Since the onset he had vomited repeatedly, and had returned everything that he had taken. The vomit consisted merely of the food he had attempted to eat or drink, It was not brown in colour. His bowels were opened on the first day, and there was a constipated result to an enema on the second day. Since then the constipation had been absolute. He had never had diarrhœa or been troubled with his bowels in any way. His right hip was ankylosed and he had been treated for tuberculous disease about five years previously. On admission: Temperature 97° F. Pulse 80. Tongue slightly coated. The abdomen was distended and showed a definite ladder pattern with visible peristalsis. There was no ascites. The liver was not enlarged and no lump could be felt in the abdomen. On rectal examination scybalæ could be felt. An easily reducible left inguinal hernia was present. There were numerous scars over the right hip, one of which was discharging yellowish pus.

Operation.—An incision was made over the left rectus below the umbilicus, the muscle was split, and on opening the abdomen a small quantity of straw-coloured fluid was found. The small intestine was distended, but the cæcum was empty. The intestines were matted together by old fibrous adhesions. On tracing the distended intestine down a sharp kink was found, produced by a thick fibrous band attached to the mesentery and to the intestine midway between the mesenteric and the anti-mesenteric borders. This band was divided and the gut above emptied itself gradually past the stricture. The wound was closed in layers.

The patient died about 24 hours later with symptoms of ileus.

Post-mortem report.—Hæmorrhagic partial necrosis, in places almost perforated, of a knuckle of ileum (6·5 cm. long) situated 183 cm. above the cæcum. This portion of gut lies free in the peritoneal cavity. Great distension and a few submucous hæmorrhages in small intestine above strangulation. Very slight fibrinous adhesions between coils of gut throughout abdomen, but no evidence of tuberculosis in these adhesions. Large indirect inguinal hernial sac left, reaching to bottom of scrotum and containing an easily reduced portion of pelvic colon. Collapse of large intestine. Great acid digestion of lungs with congestion. A few fibrous scars producing puckering of pleura apex of left lung. No fibrous pleural adhesions. No tuberculosis of mesenteric glands. Brown atrophy of the heart. Numerous puckered scars, some of them with shallow ulcers covered by scabs, around the right hip-joint. Considerable mobility in the joint.

Remarks on Cases.

The points of interest in these cases are: (*a*) The varying ages of the respective patients; (*b*) the unusual nature of the causes of obstruction; (*c*) the impossibility of diagnosing the actual cause of obstruction before operation; (*d*) the length of the history in the last three cases; (*e*) the fact that in Case 3 apparently a previous strangulation had reduced itself three days before.

I am indebted to Sir Hugh Rigby and Mr. Robert Milne, under whom the cases were admitted, for permission to publish them.

A CASE OF

CORNEO-SCLERAL CYST.

By H. Haward Bywater, M.D. Vict., F.R.C.S. Edin.,
HONORARY SURGEON, ST. PAUL'S EYE HOSPITAL, LIVERPOOL;
AND
P. Eldon Gorst, M.B., Ch.B. Liverp., M.R.C.S., L.R.C.P. Lond.,
HONORARY ASSISTANT SURGEON, ST. PAUL'S EYE HOSPITAL, LIVERPOOL.

THE case is remarkable for the size of the cyst, which, being situated in the upper half of the right eye, extended across almost the whole length of the palpebral aperture, and caused very marked lagophthalmos.

J. C., a boy aged 9 years, fell on the spout of a kettle three years ago. His right eye was cut, and he was taken to a hospital where the eye was stitched next day. He was in hospital for three weeks, and on leaving it could only see shadows, but no swelling was noticed for over two years. When admitted to hospital he complained of no pain, but only of the discomfort and disfigurement that the swelling caused. He could still see shadows.

The cyst was roughly crescent-shaped and occupied the upper third of the cornea and the sclerotic above this and on either side. It measured 25 mm. in the horizontal direction and 12 mm. from before backwards at the point of its greatest depth. The upper lid barely covered the cyst. There was no ulceration present. There was no anterior chamber and no pupil was visible. The tension was +3. No movements were seen in the cyst.

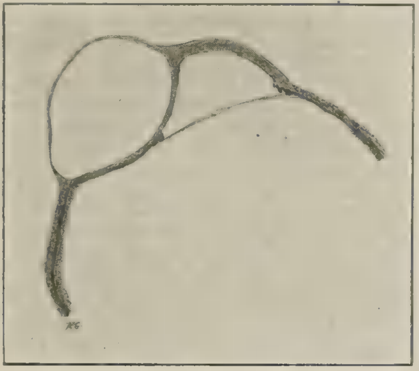

FIG. 1.—Showing general arrangement of cyst.

The eye was removed on August 14th, 1919. On section the cyst was found to contain clear fluid. It had the characteristics of an implantation corneo-scleral cyst. The iris was stretched in the vicinity of the cyst, but in front was firmly adherent to the cornea. The posterior chamber was deepened, especially near the cyst, and pigmented bands of organised lymph could be seen in front of a small and fibrous lens. No communication could be made out between the cyst and the posterior chamber. The optic nerve was cupped. The cyst was lined with squamous epithelium, which in places sent down projections which formed imperfect septa.

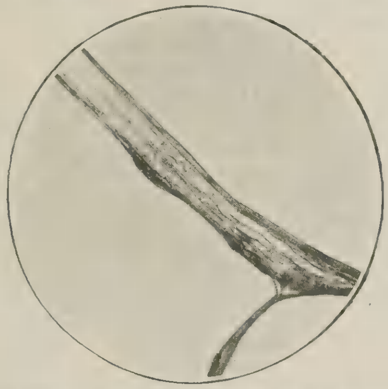

FIG. 2.—The corneal wall of the cyst, showing the corneal epithelium on one side and the epithelium lining the cyst on the other. A projection of the epithelium into the cavity of the cyst is shown.

The sections here illustrated were made by Dr. Gorst at the Thompson Yates laboratories.

WEST CORNWALL INFIRMARY, PENZANCE.—At the annual meeting of the subscribers to this institution, which was recently held, it was decided to make a public appeal for the erection of a children's ward. The cost of the scheme is estimated at £12,000, being £5000 for the building and £7000 for maintenance. It was reported that the late Mrs. D'Esta Oliver had bequeathed £3000 to the funds of the charity.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

Typhus and Relapsing Fever in Mesopotamia and Northern Persia.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 27th, Dr. A. F. VOELCKER, the President, being in the chair.

Dr. W. H. WILLCOX read a paper on Typhus and Relapsing Fever in Mesopotamia and Northern Persia. He gave a history of these two diseases and accounts of their outbreak during 1916, 1917, and 1918 in these regions, pointing out that the ætiological factors were all in accordance with the view now generally held that the body-louse is the main channel of infection of both diseases. Those factors which were associated with prevalence of the diseases which are endemic were those favourable to the life and multiplication of the body-louse. In Persia, owing to the lower degrees of maximum temperature, occurrence was all the year round, while in Mesopotamia the great heat of the summer effectively stamped out the diseases. In Lower Mesopotamia the diseases were uncommon amongst the natives owing to temperature conditions being adverse to their spread. In the Baghdad area, however, the diseases occurred practically always in the early part of each year, being, no doubt, brought along the caravan routes from Persia and the upper regions of the Euphrates and Tigris by pilgrims and others. The Turkish troops in Mesopotamia during the whole war suffered terribly.

Another source of the diseases in 1918, continued Dr. Willcox, was the influx of some 50,000 refugees from the lower Caspian region, bringing with them a heavy louse infection, as well as both diseases. In 1916 and 1917, since communication with the local Arabs in the infected areas had not been established, the main source of infection of the few cases that occurred was from Turkish prisoners. Those of our troops who came into contact with them, such as medical personnel, motor transport drivers, military guards, &c., ran serious risks of infection. After the occupation of Baghdad and large areas of Northern Mesopotamia, the troops came more into contact with the local population, so that in 1918 the main source of infection was the local population of Arabs, Kurds, and Persians. Many of these had been enrolled into native labour corps and in them both diseases occurred, so that those of our troops who were brought closely into contact with these men ran grave risks of infection; thus the medical personnel, ambulance and transport drivers, military police, and those in charge of the native labour corps were specially exposed.

As regards other channels of infection than the louse, it was pointed out that since the excreta probably contain the virus of the disease, general care as regards prevention of infection was necessary in the nursing of patients. With typhus no case was observed where the disease had spread from patient to patient in hospital, and no case was known of the spread of this disease where the agency of lice could be excluded. With relapsing fever the risk of infection appeared decidedly greater. Several instances occurred where the disease had spread from a patient to another person when every precaution had been taken to prevent access of lice. Two cases were quoted in which bacteriologists contracted the disease after taking blood from a patient for examination, in each case the usual incubation period intervened and it seemed likely that the blood of an infected person may convey the infection, also possibly the excreta in cases of a relapsing fever may serve as carriers of the disease. An unusual type of relapsing fever occurring in Northern Persia at Mianeh was described; this appeared to be conveyed by a tick known as the Mianeh bug, and the symptoms resembled those of ordinary relapsing fever such as occurred in Mesopotamia, the attacks being perhaps more severe. No opportunity of blood examination in these cases offered itself. The close association of typhus fever and relapsing fever was alluded to, and also the interesting fact that a patient suffering from one of these diseases might carry on him lice which were capable of producing both diseases. The native populations appear to have considerable immunity to typhus fever, and often had the disease in a very mild form.

The occurrence of outbreaks amongst the troops was described and the source of the different outbreaks traced. The interesting feature of the Mesopotamian campaign was that owing to the difficulties of communication, through the long distances between the posts where troops were stationed, the origin of each outbreak of disease could usually be traced, and the spread of infection effectively guarded against. At no period did these diseases get out of control, and outbreaks were quickly localised and stamped out.

Symptoms and treatment of typhus fever.—Attention was drawn to the marked severity of the mental symptoms and to the profound effect on the brain lasting many months after the fever had subsided, thus lack of concentration and inability for mental effort, associated with a condition of slight deafness, commonly lasted for at least six months. An important diagnostic symptom in the acute stage of illness was the loss of the knee-jerk, which usually disappeared about the fifth day and remained lost during the febrile stage and for a varying period after this had subsided. In severe cases a condition of coma with incontinence sometimes lasted for a week or more after the temperature had become normal. The character of the rash and its distinctions from the rash of enteric and paratyphoid and other rashes which occurred in Mesopotamia were fully described. In the treatment of typhus fever attention was called to the great value of administration of normal saline. In severe cases this was given rectally every four hours, commencing about the eighth day, and in the later stages subcutaneous and intravenous saline were given. Where symptoms of venous thrombosis threatened, an intravenous injection of normal saline containing $\frac{1}{2}$ per cent. and 1 per cent. of citrate soda was of value. The value of arsenobenzol in the treatment of relapsing fever was emphasised, and a dosage of 0·3 g. was recommended (or 0·45 g. of novarsenobenzol). Almost invariably the temperature would fall to normal within 18 hours, and usually no relapse occurred. In a series of 241 cases treated by kharsivan only 5 per cent. showed relapses. Doses smaller than 0·3 g. were found to be inefficient, while doses greater were inadvisable, owing to the risk of hyperpyrexia. When a relapse occurred after the dose of kharsivan recommended it was usually of a very mild nature, and generally the apyrexial period was much prolonged.

The debate, continued by Dr. J. C. G. LEDINGHAM, Dr. J. A. ARKWRIGHT, Dr. WILLIAM HUNTER, and Dr. A. G. PHEAR, and others, will be reported in our next week's issue.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

The Therapeutic Uses of Oxygen.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 20th, Dr. H. H. DALE, the President, being in the chair.

Mr. J. BARCROFT opened a discussion on the Therapeutic Uses of Oxygen, which was used by him in the treatment of men who had been gassed either in battle or during the making of munitions. He described the method of oxygen administration as carried out in the Cambridge laboratory by him and his co-workers, which, he said, was of the simplest character, as, owing to the treatment being experimental, they desired that the patient should be subjected to only one altered condition of life—namely, the composition of the atmosphere which he breathed. For this reason they avoided all types of apparatus for the administration of oxygen through a mask or otherwise, considering that a second variable was introduced by hampering the patient with apparatus. A glass room of about 1000 cubic feet in capacity formed a tiny ward. In this were three beds. The ward was gas-tight and fitted with air-locks large enough to serve the entrance and exit of the patients. Small air-locks were provided for the admission of food, &c. The composition of the atmosphere was kept at about 40 to 50 per cent. of oxygen and 50 to 60 per cent. of nitrogen. The carbonic acid and aqueous vapour were removed by the passage of the gas through an external circuit, which contained scrubbers of soda lime and calcium chloride. The patients were put in the chamber from about 5 P.M. till 10 A.M. for five consecutive days. The cases were all of a chronic character. In a chronic case of poisoning with chlorine, phosgene, or chlorpicrin the patient usually complained of nocturnal attacks of dyspnœa, with which might be associated sleeplessness, or physical distress out of proportion to the exertion which caused it, or both. Of these two the exaggerated response of the system to exercise offered a better mark for objective expression than did the nocturnal dyspnœa. The problem of how an exaggerated response to exertion might be stated in terms of units was one which had concerned many workers within the past few years. The response either of the circulatory or the respiratory system might be taken as the guide. Each had its advantages and its drawbacks. The pulse was easy to count, its variations in rate were susceptible of simple and accurate statement, but its significance in relation to the strain put upon the heart or the volume of blood propelled round the body was obscure, whilst the mechanism of its regulation was, at the time the experiments were carried out, also obscure. The respiratory system was in some respects more hopeful, for not only could the frequency of the respiratory system be measured but the total ventilation, the composition of the air expired and of that retained in the lung, and the depth of respiration, could all be recorded. On the other hand, the respiration was, to a much greater extent than the pulse, under the influence of the will, and therefore the records when obtained were to that extent of more doubtful value.

In the first 14 cases studied the response of the pulse to effort was taken as the criterion, in the last 12 the respiratory response.

Pulse as an Index of Effort Syndrome.

The procedure, as far as the pulse was concerned, was as follows. After a general examination of the patient had taken place he was made to rest for 15 minutes; his pulse was then counted. He was then given an exercise to perform, the severity of which was judged appropriate to his condition. His pulse-rate was counted again when the exercise was completed, and the time observed from the end of the exercise till the pulse had dropped to within six beats of its resting-rate. In nearly every case the pulse of the gassed man took an unduly long time to return to its normal. After the treatment the man was given the same test as before it.

Tables were then shown of the 14 cases, giving the recovery times of the pulse after specified exercises. All received benefit. With regard to the permanency of the effect on pulse, several of the patients were examined two and a half months after treatment, when it was shown that there was great improvement as compared with the original condition; three of them were normal (as compared with a healthy man doing the same exercise), two were nearly so, and one was improved, though his condition was not quite so satisfactory as immediately after treatment.

The Red Blood Corpuscle Count.

A sign which was frequent but by no means invariably present in cases gassed with phosgene or chlorine was a high red blood corpuscle count. It was largely the occurrence of this sign which suggested the oxygen treatment to Mr. Barcroft and his co-workers. Occurring, as it does, in persons exposed to atmospheres deficient in oxygen, they argued that the normal atmosphere to these patients presented an oxygen deficiency, and that therefore an increase in the oxygen inspired might reduce the red blood count to a normal value. The results of treatment were satisfactory, for not only were the high blood counts reduced to normal during the treatment, but the blood counts which were normal before the treatment remained normal throughout. Two and a half months after the treatment counts were made in several cases, and in none was it very high, the highest being 6·2 millions. None of these, however, had very high blood counts to start with.

Nocturnal Dyspnœa.

The third sign to which a good deal of attention was paid was nocturnal dyspnœa. The treatment was satisfactory to the extent that out of six cases in which these attacks were a marked feature only one showed no improvement. In one case they were much improved, thought not completely abolished, whilst in the other four cases the attacks were completely and permanently abolished. No man had an attack during treatment. Much more stress could be laid on the abolition of the dyspnœic attacks but for the fact that they were signs of a much more subjective type than persistent quickening of the pulse on exercise or high red blood count.

With regard to the question as to whether these results could be attributed to some subjective cause, the following points should be considered: (1) As regards the red blood corpuscle count, it was extremely unlikely that the numbers should drop from, say, 7·5 millions to 5 millions as the result of suggestion. Moreover, in gassed rabbits precisely the same phenomena occurred. (2) As regards the pulse, 12 cases of D.A.H. not attributable to gas poisoning were given oxygen treatment. These, taken as a whole, showed no clear benefit from the treatment. There seemed no reason why these pulses should not be as susceptible to suggestion as the gassed cases. (3) As regards the nocturnal attacks, in the case of one man a pantomime was enacted of blowing in oxygen in such a way as to make him suppose that he was getting the treatment, whilst the oxygen was expelled from the chamber unknown to him as rapidly as it entered. He complained that the treatment did him no good and that his nights were not improved; on the fourth night the treatment really commenced and the man at once improved.

DISCUSSION.

Dr. G. H. **HUNT** described the method by which they measured the decrease in breathlessness, and the improvement in this respect, after treatment, of the gassed men. It was realised that the main difference in the breathing of healthy and breathless men lay in the time taken for each to recover from the exercise and return to the condition shown at rest. An estimation of the time taken after exercise for the respiration to return to its pre-exercise conditions was found, for many reasons, to be impracticable. Instead of this they compared the total ventilation after exercise with that at rest, and estimated the relation between the total ventilation during the second, third, fourth, and fifth minutes after exercise with that during four minutes when the subject was at rest. By dividing the former by the latter they obtained a figure which they called the "dyspnœa ratio." This they found fulfilled their requirements satisfactorily, for it was reasonably constant for the same individual doing the same amount of work in a given time; it was approximately the same for eight healthy men who were in good "training," and for four who were in bad "training," and clearly distinguished healthy men from those suffering from any disease known to cause dyspnœa. It was also possible to measure in foot-pounds the efficiency of a man—that is, the amount of work he could do with the degree of dyspnœa which was experienced by a trained man doing 10,000 foot-pounds in 1½ min. Having obtained a standard by which a man's efficiency could be gauged in terms of work, it was possible to measure the degree of improvement produced in "gassed" patients by oxygen treatment. In summarising the results of oxygen treatment Dr. Hunt said that of 12 patients, eight improved considerably, three improved slightly, and one did not improve.

Dr. J. S. **HALDANE** pointed out that even a very small degree of anoxæmia (deficiency of free oxygen in the blood) would, if given time, have a serious effect on the individual. This was exemplified in mountain sickness, in which the symptoms were due to the effect of anoxæmia on the nervous system. The same was true of carbon-monoxide poisoning. Anoxæmia was a common condition among ordinary patients, and it was worth while taking early measures to prevent it; for if serious anoxæmia was allowed to go on for a considerable length of time the patient got into a hopeless condition. This was seen particularly in carbon-monoxide poisoning. With regard to the existence of anoxæmia in acute cases, there was important American evidence in papers in the *Journal of Experimental Medicine* for September, 1919, by Stadie and Harrup. They took examples of arterial blood from the radial artery and determined the deficiency in saturation of the arterial blood. Stadie's cases were principally pneumonias of different types. In practically all there was a deficiency in saturation of arterial blood. In some it was as great as 50 per cent., and with such a deficiency the patient always died. There was a deficiency in croupous pneumonia even when the patient was going on well. There were two causes for the arterial blood in the lung not being properly saturated. The first was that the epithelium had become thickened and clogged by exudation, so that the rate at which the oxygen got into the blood was very much diminished, and there was not time for the blood to get saturated with it as it passed through the lungs. This was what occurred in acute lung-irritant gassing. The second cause was unequal expansion of the lung or an unequal rate of entry of air into the alveoli, so that some alveoli would contain too little oxygen to saturate the blood, whilst in others there would be more than sufficient. This was revealed by the experiments of Professor Meakins, Dr. Priestley, and himself at the Taplow Canadian Hospitals in chronic gas cases. This latter condition could be brought about in the normal person by shallow breathing, which was one of the defects in the so-called chronic cases of gassing. In the case of himself, when in consequence of shallow breathing his respiration rate was increased to 30 or 40, Cheyne-Stokes breathing developed in two or three minutes, and this was abolished by adding a little oxygen to the inspired air. In his and Dr. Priestley's experiments the alveolar air during shallow breathing was normal, and yet there was arterial anoxæmia. In bronchitis and such conditions the distribution of air among the alveoli was interfered with by resistance, so that anoxæmia might occur although the lung epithelium was healthy. In chronic gas cases the patients were short of breath, although the lungs appeared to be all right, as judged by examination with a stethoscope. If a gassed man went on working or walking his breathing became rapid and ineffective, and there would be perhaps only 1·5 per cent. of carbon dioxide in the expired air. The shallow breathing was dyspnœa and not simply hyperpnœa. These chronic gas cases had respiratory neurasthenia, causing shallow rapid breathing on exertion, instead of slower deep breathing. In these and similar cases there were also attacks of very rapid shallow breathing, with urgent asphyxial symptoms. The acute attacks often occurred at night. The experiments carried out at Cambridge and Stoke-on-Trent were of great interest as showing how such patients could be helped by putting them into an atmosphere of air enriched with oxygen. The bad attacks did not occur; sleep was sound, and they thus had a proper chance of rest and recovery.

Colonel S. L. **CUMMINS** thought that although it was certain that oxygen could do much good in the acute case of gas poisoning and in influenzal bronchopneumonia and shock, in both of which there was an element of anoxæmia, yet there was a feeling of reluctance on the part of the medical officers to use oxygen. This, he thought, was due to the difficulty in administering oxygen, either through a face mask or by means of an apparatus, to a man suffering from intense anoxæmia, with much nervous irritation and great difficulty in getting breath at all.

Acute Gas Cases in France.

Dr. C. G. **DOUGLAS** spoke of his experiences in France, where the gassed cases were seen in the acute stage. He said that it was obvious after the first gas attack that oxygen administration did some good to patients with cyanosis resulting from acute pulmonary œdema. After an interval of some months a batch of patients arrived, many of whom were in the gravest condition. They were either deeply cyanosed, of a purple colour, obviously short of oxygen, or they had that grey colour of lips and tongue which is associated with a profound deficiency of oxygen and collapse. At first efforts were made to give oxygen by means of a simple tube and funnel. The next stage in the development of oxygen administration was the nasal tube method, which was improvised by Adrian Stokes after a very serious gas attack. About the same time Haldane produced his apparatus. There was no doubt that an enormous amount of good could be done by administering oxygen by some such suitable method. Dr. Douglas then described two cases of severe acute gas poisoning which were improved and eventually cured by the administration of oxygen alone. Sometimes gas casualties were admitted in a very grave condition of collapse and pallor, and the medical officer found that by treating them with oxygen for a couple of hours or so considerable improvement set in, and venesection could then be carried out with advantage.

Dr. J. A. **RYLE** spoke of his experiences after a gas attack in 1916, when oxygen was administered by Captain Adrian Stokes by means of the nasal catheter. Dr. Ryle had applied the method then and frequently afterwards with very great success. To the tube leading from the oxygen cylinder was attached a No. 8 rubber catheter. This was lubricated with vaseline and passed directly along the floor of the nose to a distance of four inches into the naso-pharynx; the catheter was looped up to the side of the face and fixed there by strapping and the oxygen allowed to run in gently. By that means it was possible to give oxygen for as long as 72 hours. He had frequently seen men admitted in a state of grey pallor and cyanosis (such as one associates with extensive œdema of the lungs produced by phosgene) with an almost imperceptible pulse and, on several occasions, a respiration-rate of over 60, in a semi-conscious condition, cold, and collapsed. After 72 hours of oxygen inhalation the respirations became reduced to 24, the men made a steady recovery, and were fit to travel down the line by train without accident. One of the chief obstacles to the use of the Haldane mask was the fluid and froth which the men got rid of by the mouth in bad cases of lung œdema. As much as a pint of serous froth might be poured out in a few hours. It was very important that the mouth be kept clean and free from froth, and care must be taken that the mask does not become clogged by the froth. It was necessary also to give the patient fluid nourishment, and occasionally even some solid food, and this was possible when they were having oxygen through the catheter. The cases were classified into three groups. The mildest were the cases which needed merely the oxygen they could get by being out-of-doors; the medium cases seemed to be sufficiently benefited by a small dose of pure oxygen from a nitrous oxide bag given at intervals of five minutes in every quarter of an hour, sometimes at longer intervals; finally, there were the severe cases, for which continuous inhalation of oxygen was obviously the only form of treatment. It was found to be impracticable to pass a nasal catheter down each nostril on account of deflections in the nasal septum blocking up one nostril. Subsequently he used the catheter method, not only for gas cases, but also for the lung œdema of trench nephritis, a condition which gave a closely similar clinical picture to that produced by phosgene.

Dr. R. A. **PETERS** described a severe case of Bronchopneumonia, with Cheyne-Stokes breathing, which he had treated by oxygen administered by means of the Haldane apparatus, with marked success.

Work of the Medical Research Committee on Oxygen Research.

Dr. FRANK **SHUFFLEBOTHAM** described the work which had been done on oxygen research under the auspices of Sir Walter Fletcher and the Medical Research Committee at the North Staffordshire

Infirmary, Stoke-on-Trent. The wards were opened in October, 1918, and up to the present time over 100 cases had been admitted. The cases included for the most part those of chronic gas poisoning, but in addition there had been cases of acute gas poisoning, pneumonia, carbon-monoxide poisoning, and two cases of pernicious anæmia. The patients suffering from chronic gas poisoning derived great benefit from this treatment in the general state of their health, and in many instances symptoms of long standing such as cough, shortness of breath, expectoration, asthma, and irregular action of the heart became less severe in nature and frequently disappeared. The physical condition of the lungs and heart also underwent a considerable improvement. Dr. Shufflebotham quoted from the report to the Medical Research Committee an account of the technical details connected with the construction and working arrangements of the chamber. The estimation of the amount of oxygen and carbon dioxide is carried out by the Haldane apparatus. With regard to the cost of oxygen treatment, Dr. Shufflebotham said that at Stoke-on-Trent, where the strictest economy had been exercised in regard to the supply of oxygen to the wards consistent with the percentage of oxygen in the atmosphere being in excess of 40 per cent., and in spite of all efforts to control expense in every direction, it had not been possible to bring down the daily cost per patient to less than £1 3*s.* 6*d.*, not including any sum which could be attributed to capital charges. With pneumonia cases the cost was such that it was very likely to handicap research in this direction, unless money was forthcoming from further grants or philanthropic sources. The high cost of oxygen was due to the fact that the production of oxygen in this country is in the hands of a monopoly. It had been suggested that instead of pure oxygen from the cylinders it might be possible to use the by-product of the air after the nitrogen had been extracted from it. Another suggestion was that liquid air, which contained about 60 per cent. of oxygen, could be used for these cases. He was convinced that there was a great usefulness for oxygen treatment as well as a great field for research, and, considering the amount of human suffering which might be alleviated by such treatment, it seemed almost a scandal that the work should be handicapped because of an oxygen monopoly.

Account of 70 Gas Cases.

Dr. G. H. SOWRY gave an account of 70 cases of gassing. In all cases the gassing had occurred at a more or less distant date, varying from four months to over two years. In most cases the nature of the gas could not be ascertained, though in the earlier cases it was probably chlorine, later phosgene, and later still "mustard gas." The patients were admitted for periods of five or six days, and remained in the chambers for about 20 hours each day, being allowed out for exercise for about four hours each afternoon. The chambers were surcharged with oxygen, the percentage being between 35 and 40 in the earlier cases and from 50 to 60 in the later. After their discharge they were asked to report for examination two, four, and six weeks later. Before treatment the patients were examined and notes made as to: 1. Subjective symptoms such as cough, expectoration, sleeplessness, dyspnœa and palpitation on exertion, asthmatic attacks, &c. 2. Objective signs as revealed by a clinical examination of heart and lungs. 3. The chest was X rayed. 4. An examination of the blood was made, the red cell count and hæmoglobin percentage being noted. 5. The response to effort was tested by three tests—(*a*) short violent effort, by swinging of arms; (*b*) medium effort, by going up and down stairs; (*c*) prolonged effort, by walking round the hospital grounds.

Symptoms on admission.—Most patients complained of (1) cough and expectoration; (2) dyspnœa, palpitation, and præcordial pain on exertion; (3) attacks of nocturnal dyspnœa in all essentials like true spasmodic asthma; (4) sleeplessness; (5) low appetite and dyspepsia; (6) mental depression.

Physical signs on admission.—Lungs: Emphysema was present in about 40 per cent. of the cases. Nearly all of them exhibited râles, rhonchi, or crepitations over the whole or part of the lungs. In many cases over the lowest three or four inches of the bases behind there were slightly impaired resonance and fine crepitations. X ray examination in nearly all cases showed a condition of fibrosis, especially near the roots of the lungs. The appearance of the plates suggested a condition of peri-bronchial phthisis, but in only two cases had he proved the existence of active tuberculosis. If the condition was one of true fibrosis there could be little hope of a permanent cure. Heart: Only a few cases of V.D.H. were found, and in about ten cases there was hypertrophy. The most obvious condition found was a very poor response to effort. At rest the heart sounds were in most cases clear and the action regular, though in a little less than half, there was some irregularity with extra-systole. Even slight exertion in nearly all cases caused a great increase in pulse-rate, with marked irregularity. Nervous system: Very few showed any physical signs of organic disease beyond increased tendon reflexes and some vaso-motor instability.

Results of treatment.—1. Immediate. In the large majority of cases the patients were decidedly better for the treatment. They felt brighter, more cheerful, and more energetic. Their appetites improved, and their digestions were better. Sleeplessness in most cases lessened, and where patients suffered from asthmatic attacks this symptom disappeared. Coughs improved, and expectoration was reduced. The response to effort—as measured by the tests—generally appreciated, in most cases considerably. It was difficult to estimate numerically the results, but a careful classification justified him in saying that of the 69 cases reported upon 23 were very much improved, 30 were much improved, 10 were improved, and 6 were not improved. 2. Later. The later results, as estimated on the last examination (usually six weeks after the end of treatment) were, on the whole, very satisfactory, though there was certainly a tendency for some of the original improvement to be lost. Numerically expressed, of the 60 patients who reported 15 were very much improved, 22 were much improved, 10 were improved, and 13 were not improved. Dr. Sowry then considered the effect of treatment on each of the common symptoms. Besides these cases of gas poisoning other diseases were treated. Two cases of pernicious anæmia were treated with unfavourable results. Five cases were treated, where the predominant symptom was respiratory difficulty, and in all the results were so good as to be almost startling. It was in these cases that he thought the value of treatment in oxygen chambers offered the highest hopes. The five cases comprised two cases of severe acute gas poisoning, one case of coal-gas poisoning, one case of broncho-pneumonia with emphysema in a child aged 3 years, and one case of acute lobar pneumonia, with complete consolidation of the whole of both lower lobes. All these five cases suffered from want of oxygen in a severe form. They all improved almost immediately they entered the chambers. Dr. Sowry was convinced that treatment by the continuous inhalation of a *warm* atmosphere, surcharged with a known percentage of oxygen, held great promise in the treatment of many diseases.

Dr. P. HAMILL spoke of the effects of oxygen administration in cardio-vascular disease and opium poisoning. Oxygen in high concentration abolished the heart-block and maintained the blood pressure at a uniform high level during the apnœic period of Cheyne-Stokes respiration. With the improvement in circulation there was in some cases a return of consciousness. Satisfactory results could only be obtained with a concentration of 40–50 per cent. for hours at a time. The nasal tube was satisfactory but wasteful. Most methods of administration by a mask necessitated the constant attendance of a nurse and were almost equally wasteful. There was a great need for a simple portable apparatus on the lines of that used for insufflation anæsthesia, in which oxygen could be circulated and the CO_2 absorbed. On the grounds of portability and cost sodium peroxide had much to recommend it as a source of oxygen in preference to cylinders.

SECTION OF ODONTOLOGY.

DENTAL SEPSIS IN CHILDREN: ITS CONSEQUENCES AND TREATMENT.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 26th, Sir JAMES COLYER, the President, being in the chair, when Mr. F. ST. J. STEADMAN read a paper on Dental Sepsis in Children: Its Consequences and Treatment. The paper is published in the front part of the present issue of THE LANCET.

DISCUSSION.

In the course of the discussion which followed,

Mr. F. N. DOUBLEDAY said that the function of the teeth was very important, but he agreed that where sepsis was established and the teeth functionless, they were useless and redundant and should be removed.

Mr. F. B. BULL spoke of the importance of the nervous system of the child, which in many cases was such that it was impossible to carry out treatment. Teeth which were septic should be removed at once. He agreed that extensive extraction could be done under ethyl chloride on the open mask.

Dr. ARTHUR SAUNDERS laid emphasis on the excellent results which he had seen in children at the West London Hospital after treatment of the teeth. The children with septic teeth, in addition to being anæmic and wasted were often slightly cyanosed and night sweats were present, so that tuberculosis was often suspected; the heart, too, was often slightly dilated, a condition which he considered to be due to a mild septic myocarditis which cleared up after removal of the septic teeth. Slight albuminuria was often present, and nephritis sometimes supervened. Some acute cases of hæmorrhagic nephritis due to dental sepsis reminded him of similar cases occurring after scarlet fever.

Mr. E. B. DOWSETT said that the way in which children were able to eat after all the teeth had been removed was remarkable. Those whom he had been able to follow up were able to eat even meat, and thrived well. The occurrence later of irregularity was the only bugbear, but possibly this need not be considered seriously owing to the enormous advantage which followed thorough treatment.

Mr. A. T. PITTS said that Mr. Steadman had brought a serious indictment against the medical and dental professions in stating that some members of both professions did not recognise the serious effects of dental sepsis in children. His experience at the Hospital for Sick Children enabled him to endorse all that Mr. Steadman had said with regard to the gravity of the problem and the results of adequate treatment. The effects of dental sepsis, both local and general, were apparent, and equally striking was the improvement in the general health when the mouth was rendered clean. Even where the mouth had to be left practically edentulous the children put on weight and were able to eat their food in comfort. It was astonishing that any man with a medical training should fail to see the harm arising from septic teeth. Frequently mouths were seen in which necrosed roots had ulcerated through the side of the gum, a condition comparable to sequestra being exfoliated. No doctor would regard such a condition occurring elsewhere with complacency, and yet it was sometimes allowed to exist unnoticed in the mouth. It was true that premature loss of the deciduous teeth often led to irregularity of the permanent teeth, but this lesser evil was so completely outweighed by the greater evil of dental sepsis as to be not worth considering. Some had said that this irregularity was a common predisposing cause of pyorrhœa in later life. In his opinion dental sepsis in an adult whose metabolism had reached a state of equilibrium was less serious than sepsis in a growing child who needed nourishment, not merely to replace the daily loss of energy, but to increase the bulk of its tissues.

Mr. LEWIN PAYNE laid stress on the need for prophyctic treatment. Adequate instruction should be given o parents and children, or the condition would recur u two or three years.

Mr. J. G. TURNER said that extraction was necessary in order to get rid of sepsis. The need of the poor children of London for dental treatment was urgent. All the dentists in the British Isles would not suffice to do all the stopping which should be done. Myopia might result from dental sepsis, the sclera becoming affected by toxæmia or by the malnutrition which accompanied the condition.

Mr. GEORGE THOMSON, speaking of tuberculosis in school children, said that dental sepsis affected the child in two ways: (1) allowed the infection by pathogenic germs and (2) by resulting malnutrition. The school dental treatment scheme broke down because there were an insufficient number of dentists available. Treatment must be begun earlier. He had removed incisors in children of 15 months. The incisors of babies became denuded of enamel owing to the sugar-bag which was given them by their mother when going to sleep.

Mr. G. NORTHCROFT and the PRESIDENT also spoke, and Mr. STEADMAN replied.

MEDICAL SOCIETY OF LONDON.

EXHIBITION OF SPECIMENS.

A PATHOLOGICAL meeting of this society was held on Jan. 26th, Mr. V. WARREN LOW, the President, being in the chair.

Congenital Dilatation of the Ureter.

Dr. C. E. LAKIN showed two specimens illustrating Congenital Dilatation of the Ureter. The first consisted of the bladder, ureters, and kidneys, and was removed from a male child 17 days old, who had had a slight degree of hypospadis and phimosis. The ureters showed a high degree of dilatation, the lower part of the right ureter being as large as an adult cæcum. No difficulty was experienced in passing a probe through the orifices of the ureters where they opened into the bladder. The position of these orifices was unusual; not only did the right ureter enter the bladder at a higher level than the left, but both entered the bladder much nearer the fundus than usual. The bladder was not distended. The urachus was only partially obliterated. There was relatively only slight dilatation of the pelvis of the kidney, so that the specimen appeared to be described more correctly as one of congenital dilatation of the ureters than of congenital hydronephrosis. The second specimen was the right ureter and kidney, removed from a boy, aged 10, by Sir Alfred Pearce Gould. No obstruction existed at the lower end of the ureter. The boy had had a swelling in the right side of the abdomen most of his life, but latterly the swelling had increased in size. The patient made an excellent recovery. The ureter was enormously dilated, exceeding an adult colon in size.

Mr. E. PEARCE GOULD thought that the dilatation might be explained by increased intra-ureteric pressure brought about by the abnormal course of the ureters in the bladder wall.

Dr. FREDERICK LANGMEAD compared the condition to megalocolon, and to œsophageal dilatation, in each of which structural obstruction was often absent. Sometimes a group of such dilatations was met with in the same infant, and he thought their explanation lay in irregular muscular action of the involuntary muscle. He had removed after death a specimen closely similar to the first example shown by Dr. Lakin.

Dr. B. H. SPILSBURY agreed in ascribing the dilatation to abnormal neuro-muscular action. The dilatation in the first case was too great to have occurred after birth from mechanical causes, acting during so short a period as 17 days.

Status Lymphaticus.

Dr. LAKIN also showed two portions of intestine from a case of Status Lymphaticus. The patient was a girl, aged 7, who died while under anæsthesia about 15 minutes after the anæsthetic was begun. The specimens showed the usual enlargement of Peyer's patches and solitary follicles. There was enlargement, also, of the thymus and mesenteric glands, and the wall of the right ventricle of the heart was unusually thin.

Multiple Neurofibromata.

Dr. J. G. **GREENFIELD** showed some specimens from a case of Multiple Neurofibromata. During life the diagnosis of cerebral tumour at the cerebello-pontine angle had been made, and subtentorial decompression was performed by Mr. Donald Armour. Before the operation cutaneous neurofibromata were detected and led to the suggestion that the intracranial tumour was of the same nature. After death tumours were found on both acoustic nerves and on spinal nerves near the spinal cord. Another was connected with a semilunar ganglion. In the latter the nuclei of the tumour cells showed a "palisade" arrangement. In Dr. Greenfield's opinion neurofibromata originated from the sheath of Schwann, which explained why they are not found in association with the optic and olfactory nerves.

Congenital Heart Disease.

Dr. **SPILSBURY** showed the heart of a woman, aged 35 years, who had died from Congenital Heart Disease. There was sufficient patency of the ductus arteriosus to admit a finger. Spontaneous rupture of the pulmonary artery into the pericardium had occurred, and had been brought about by atheroma, which was visible at the margins of the tear. Old rheumatic disease of the tricuspid and pulmonary valves were associated.

Dr. **SPILSBURY** also showed a series of specimens illustrating sudden death from Pulmonary Embolism. In the subsequent discussion it was held that thrombosis of peripheral veins, and consequently embolism of pulmonary artery, occurred independently of sepsis.

Dr. **SPILSBURY** also showed a Coral Calculus from the Urinary Bladder.

Protein Reactions.

Dr. J. **FREEMAN** demonstrated the conjunctival and cutaneous reactions obtainable in patients who are susceptible to various proteins. In the case of hay fever it was shown that a diluted extract of grass pollen, if instilled into the conjunctival sac, produced a harmless and transient injection, while if a tip of a glass rod was charged with the pollen and rubbed into a square scratch in the skin an irregularly shaped wheal resulted. Quantitative testing could be carried out with known dilutions of the extract. Susceptibility to other pollens, to the protein of horses and other animals, and to various kinds of food, fell into the same group, and the symptoms varied only in accordance with the anatomical position to which the disturbing protein was applied. Thus, the severe vomiting and diarrhœa which prostrated some persons who ate eggs or strawberries was of the same nature as the prostration and catarrhal changes in the upper respiratory passages in hay fever. The tests were specific and denoted which was the particular protein to which a patient was susceptible. Experiments had shown that when a susceptibility to a protein was encountered in an individual other members of the same family often showed a susceptibility to other proteins. With regard to the pollens, that of grass was the only one of importance, though certain persons were susceptible to others. This was explained by its abundance and its lightness, the others being relatively much heavier. Another method of employing the test was to precipitate the protein to be tested out of a watery solution by an excess of alcohol. The solution was then filtered and the filter-paper with its attached precipitate dried. A small square of this paper, protein-side downwards, if superimposed on a scratched surface, gave the cutaneous reaction. Only sufficient protein to give the faintest opalescence to the solution was enough to give the reaction.

Dr. A. **FLEMING** demonstrated the methods of testing donors' blood in the technique of blood transfusion.

Mr. **DONALD ARMOUR** showed specimens of (1) Right Frontal Abscess following a gunshot wound of the right orbit in which suppurative meningitis had been limited to the *left* vertex and base; (2) Scirrhus Carcinoma of the male breast; (3) Renal Abscess. The case was one of a group which had been under his care during the time when perinephritic suppuration was prevalent. His cases supported the contention of those who held that the suppuration around the kidney was secondary to infection of the kidney itself.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

AT a recent meeting of this society Dr. C. **SCHMITT** read a paper on

Radium and X Rays.

Of eight cases of cancer of the uterus treated by him with radium since last March four had made so much improvement that they regarded themselves as cured; one patient was in a very satisfactory condition, one had been lost sight of, the seventh was progressing favourably though the treatment had been very irregular, and the eighth case had survived more than five years. He agreed with Béclère in regarding radiotherapy as applicable to all uterine fibroids, apart from certain cases in which urgent operation was required.

In a communication on

Biological Medication,

Dr. A. **DARIER** discussed the action of normal and antitoxic serum, vaccines, and all biological agents such as exudates, filtrates, tissue extracts, organic fluids, bacterial cultures, and colloids. He dealt particularly with hypodermic injections of cow's milk, which were first employed by Muller and Thanner of Vienna in 1916 and had yielded good results in the treatment of gonorrhœal arthritis, eye diseases, especially iritis, articular rheumatism and influenza. The action of parenteral injections of milk, peptone, and nucleins was partly to be explained by the febrile reaction caused by introduction into the blood-stream of a foreign albumin and partly by the stimulation of leucocytosis and phagocytosis. In severe infections Dr. Darier had derived much benefit from the combination of injections of diphtheria antitoxin or polyvalent serum with injections of milk. As the latter could only be given every other day owing to the febrile reaction which they caused, he gave on alternate days an injection of serum which had a sedative and analgesic action in addition to its power in combating infection. He had found that the alternate use of injections of milk and serum greatly reduced the frequency of serum complications.

In a paper entitled

The Legend of Arsenic in Dermatology,

Dr. **CARLE** (Lyons) said that when a drug enjoyed such a persistent and general vogue as arsenic, the vogue could generally be explained by the following: (1) The influence of authority; (2) the knowledge of precise experimental facts proving its action; (3) clinical observation of numerous well-established cures. The revival of arsenic in therapeutics dated from the beginning of the nineteenth century with Fowler, Pearson, Monro, and Willan in Great Britain. Biett, who introduced Willan's doctrine into France, became an ardent supporter of the drug, and his enthusiasm was shared by Cazenave, Rayer, and Devergie. The reaction commenced in the second half of the century with Hillairet, who declared that arsenic was not a specific for any form of eczema, or, indeed, for any skin affection. Almost at the same time Vidal denied arsenic any therapeutic value, and Baumès, the dermatologist of Lyons, stated that though he had seen some improvement and a few cures, he had witnessed a large number of gastric and intestinal complications. In German-speaking countries arsenic was as much ignored as any other internal medication in dermatology, both the school of Unna and that of Hebra regarding it as unnecessary and dangerous. Besnier, Brocq, and Audry also protested against the abuse of arsenic in the treatment of skin disease. It was therefore clear that the leaders of French dermatology were not responsible for the vogue which arsenic enjoyed in France. Dr. Carle next showed that experiments had not proved the favourable action of the ingestion of arsenic either on the skin or on the general condition. In his practice he had found that treatment of skin affections with arsenic, often in large doses and for a long period, yielded no appreciable result. Comparison with the results obtained by the local use of coal-tar preparations had been so much in favour of the latter that since 1905 he had never given a single dose of arsenic in cases of eczema, psoriasis, para-keratosis, lichen, or other skin conditions. He concluded that the reputation of arsenic was in great extent due to its having been used in cases such as erythema, herpes, pityriasis rosea, and other cyclical dermatoses which had a tendency to spontaneous recovery, and also to the demands of the patient, who was convinced of the value of an internal remedy.

In a paper on

The Dangers of Autoserotherapy,

Dr. Victor Cordier (Lyons) related the case of a soldier, aged 26, admitted to a tuberculosis ward with slight lesions of the right apex, and a painless swelling, the size of a large hazel nut, in the abdominal wall. The patient had been treated by autoserotherapy for tuberculous peritonitis five years previously. On incision the swelling proved to be a cold abscess containing tubercle bacilli. Dr. Cordier concluded that autoserotherapy was not merely a useless, but also a dangerous, method. Similar accidents had been recorded after pleural autoserotherapy.

Dr. H. Bourges reported a case of

Intoxication by Syrup of Belladonna

in a child aged 14. He alluded to a similar case, published by Merklen, in a child of the same age, after taking the syrup prepared according to the French Codex of 1884. Although the Codex of 1908 had reduced the quantity of active principles contained in the syrup by a third, its administration was not yet free from danger, even when given in small doses at a time and well diluted. The present patient was a girl, the subject of pulmonary tuberculosis, suffering from frequent spasmodic cough and night sweats. 15 g. of syrup of belladonna in 120 c.cm. of water were ordered to be taken every 24 hours in small doses. After the first few doses the child became very restless, complained of headache and dryness of the throat, and kept calling for something to drink. On his visit next morning Dr. Bourges found her neck, face, and trunk covered with a pruriginous scarlatiniform eruption. The pupils were dilated and sluggish in reaction. The urine was scanty and red. The temperature was 103·2°, the pulse 130, and the respirations rapid and laboured. The medicine, which had been given throughout the night, was stopped, and 48 hours later the rash disappeared. On the third day all the symptoms had subsided.

North of England Obstetrical and Gynæcological Society.—A meeting of this society was held at Manchester on Jan. 16th, Mr. Miles H. Phillips (Sheffield), the President, being in the chair.—Mr. W. Blair Bell (Liverpool) showed a specimen of Diverticulum of the Bladder with Cystitis. The diverticulum was adherent to the right ovary and was undoubtedly congenital.—Mr. Carlton Oldfield (Leeds) had often observed cases of diverticula of the bladder, but in no case had infection occurred. He suggested that a portion of the bladder wall might have been pulled out by inflammatory tissue in the neighborhood of the right uterine appendage; but Mr. Bell, in reply, did not think this probable.—The President demonstrated a specimen of Adenomyoma of the Recto-vaginal Septum in a multipara aged 45. A tender nodular cystic growth occupied the posterior fornix and presented a small area of papillary growth. No connexion with the cervical mucosa could be demonstrated. He had operated on more than 20 of these cases and considered them to be of inflammatory origin.—Dr. H. Leith Murray (Liverpool) recalled a case of adenomyoma presenting unusual features, and contributed to the society by the late Dr. Wallace in 1914.—Dr. D. Dougal (Manchester) described two cases on which he had performed Cæsarean section for Dystocia, due to (*a*) uterus bicornis unicollis and (*b*) ventrofixation, or adherent myomectomy scar. In the first case the non-pregnant horn of the double uterus lay within the pelvic brim and caused obstruction. The second patient had a myomectomy performed four years previously. The anterior uterine wall was firmly adherent to the parietes, the exact cause of which could not be definitely ascertained. The posterior uterine wall had become enormously hypertrophied and had pulled the cervix upwards and backwards to the level of the sacral promontory. Owing to the fixation the Cæsarean incision had to be made through the posterior uterine wall, and a few days after operation a coil of small intestine lying in the pouch of Douglas became adherent to it and caused acute intestinal obstruction. This was remedied at a second operation, and the patient then made a good recovery.—Dr. W. W. King (Sheffield) showed microscopic sections of a Spindle-celled Sarcoma which appeared at the lower end of a colporrhaphy wound within one month of operation, and was apparently cured by Coley's fluid.—The President thought the appearance of the section very suggestive of granulation tissue.—Dr. A. Donald (Manchester) said that the clinical picture in this case did not seem to be altogether in favour of sarcoma, and that diagnosis by microscopic examination was sometimes very difficult.—Dr. King, in reply, thought that the rate of growth was too rapid for granulation tissue. He would keep the case under observation and make a further report in six months' time.—Mr. Oldfield described a case of Hydatid Mole with bilateral ovarian cysts and toxæmia. The patient was a multipara aged 36. Her husband had contracted syphilis a year previously, and she herself had a positive Wassermann. Severe toxæmia with albuminuria developed suddenly. On examination the uterus was found retroflexed and the size of a 3½ months pregnancy. Seven days later the uterus reached the costal margin. Abdominal pain and tenderness, and marked tachycardia were present, and her general condition was grave. There was no external hæmorrhage, and the cervix was closed. Under an anæsthetic the uterus was emptied, and the contents found to be a hydatid mole. There was practically no hæmorrhage during the operation. During the pelvic examination at the time of operation bilateral ovarian cysts were discovered, the left being apparently the size of two fists. The patient recovered rapidly, and the ovarian cysts decreased, until three months later they had entirely disappeared.—Dr. W. E. Fothergill (Manchester) mentioned a case of hydatid mole, in which severe symptoms of toxæmia had necessitated his removing the uterus. However, toxæmic symptoms persisted and caused death two months later.—The President related a case where a large cervical fibroid caused severe hæmorrhage ten years after the climacteric. The patient, a spinster aged 57, had a quite sudden profuse hæmorrhage, which was only controlled by packing the vagina. A pelvic tumour had been known to exist for years, but had caused no recent discomfort. Hysterectomy was performed; the uterus was atrophied, but the cervix was lengthened to over 6 in., and extremely thinned by a large cervical fibroid. Under the cervical mucous membrane covering the lower pole of the tumour were many large veins, and it was considered that rupture of one of these had led to the profuse bleeding.

Nottingham Medico-Chirurgical Society.—At a meeting of this society held on Jan. 21st, Dr. W. Rowe being in the chair, Dr. C. H. Cattle read a paper on Cardiac Affections and the War. He said that the condition we speak of as "soldier's heart," though well known in medical literature, had now for the first time in the history of our country become familiar to every practitioner. The principal symptoms were said to be palpitation, breathlessness, cardiac pain, and giddiness. The chief causes were some infective illness, especially rheumatic fever, and the physical and mental strain of warfare. Half the cases of this affection, for which the term "effort syndrome" is an apt description, were taken from light occupations. As so many men were unable to bear strenuous exertion in civil life, the conditions of military service might be said to have rather brought out a latent tendency than to have caused this condition. Methods of identifying the commoner forms of irregularity of the heart were described. Drugs, with the exception of bromides, were comparatively useless in the "effort syndrome." The most successful method of treatment was the system of gradual physical training in a special institution, introduced by Dr. Thomas Lewis. Some of these men had systolic murmurs, but the murmur per se was found to be no bar to the attainment of a high standard of physical endurance. The general adoption of the exercise test was considered to be the greatest advance made in the examination of cardiac cases as a result of the experience of the war. The following conditions call for rejection for the army: enlargement of the heart, mitral stenosis, aortic regurgitation, aneurysm, repeated attacks of rheumatic fever, failure to pass a strenuous exercise test. A systolic murmur, in the absence of enlargement of the heart or of symptoms, is far more often functional than organic. Aortic stenosis without regurgitation is rare. The murmurs of mitral regurgitation cannot be distinguished from other systolic murmurs at the apex. But this affection, even if its existence could be proved, may be compatible with many years of useful and even strenuous life. On the contrary, the tendency of mitral stenosis and aortic regurgitation is to get steadily worse.

THE present year is the centenary of the opening of the Cornwall County Asylum, which took place on Oct. 25th, 1820, when the first patient was admitted. It is hoped that the event will be subsequently commemorated in some appropriate manner.

Reviews and Notices of Books.

THE TRANSMUTATION OF BACTERIA.

By S. GURNEY-DIXON, M.A., M.D. Cantab., M.R.C.S. Eng., L.R.C.P. Lond. London: Cambridge University Press. 1919. Pp. xviii. + 180. 10*s*. net.

TO-DAY a prominent problem of the bacteriologist is what constitutes a bacteriological species, nor can this problem be solved until he has determined what are the limits of the variability of bacteria. It is a problem that has been with us from the very beginning of bacteriology as a science. Ray Lankester was one of the first to draw attention to the subject in his studies of the *Bacterium roseo-persicinum* in the "seventies." Hueppe and Cartwright Wood, Roger and Charrin in the "eighties," Adami and others in the "nineties"—all called attention to the position, but the routine bacteriologist was satisfied to find that the majority of pathogenic bacteria, when isolated and grown upon the accepted media of the laboratory, gave the regulation reactions. For him forms which departed from type could not be accepted as proper members of the species and merited no further inquiry. With Koch and the German school in general he was a firm believer in the fixity of bacterial species. To-day, with the elaboration of bacterial technique and the consecutive examination of not an odd dozen but of a hundred or more strains, subjecting each not to two or three but to a score or so precisely adjusted reactions, he is forced to see that there is an extraordinary amount of variability, in morphology, in cultural characteristics, and in biochemical properties. Even with forms which in their morphology and cultural characters appear to be identical there may be in the matter of the fermentation of saccharoids—sugar, glucosides, and the lower alcohols—as many distinct strains as there are permutations of a series of a score of numbers.

Dr. Gurney-Dixon has performed a timely service in bringing together a large mass of data bearing upon this matter of bacterial variation and the allied question of mutation or transmutation—i.e., of the sudden development, in the course of cultivation of any one species of bacteria, of forms which diverge strikingly from type, and maintain the divergence in subsequent culture. The work, admittedly, is not complete: it is based upon British bacteriological literature; it does not pretend to present the parallel observations contained in French and German literature; nor is any account taken of the abundant and valuable observations made in the United States. Even in respect to British literature this book only includes material collected before the war; and important and more recent observations by British observers published outside Great Britain, such as those of Thiele and Embleton, are passed over in silence. It is, therefore, very far from a complete presentation of this subject. Yet admitting this, it has also to be admitted that a study of this other literature would not materially have altered the conclusions reached by the author, and those conclusions are conservative. Particularly in his own investigations, Dr. Gurney-Dixon shows himself to possess a wise scientific caution.

But what must impress the reader, both in reviewing the earlier literature and in connexion with the author's own researches, is that the methods employed thus far are, with rare exceptions, inadequate to afford a sure solution of the problem. Particularly is this the case in the study of chance variations, or "sports." If we cannot, on the one hand, reproduce the conditions under which these develop, on the other we cannot convince ourselves that these originate from individuals belonging to type strains. Unless we start by securing growth from a single microbe we cannot be sure that we have not been dealing with a mixed culture. Now such growth from a single organism was not undertaken in the observations here recorded. Even to-day, by the employment of Barber's method or a modification of the same, it is a matter bristling with difficulties, and until those difficulties are overcome we cannot be sure of the results; we deal in probabilities, not in certainties. With impressed variations the case is different; by subjecting all the members of what is presumably a pure culture to the same alteration of environment we can induce, and that constantly, the same alterations, whether in morphology or in individual properties. But even here difficulties occur; it is not so easy as it would seem to subject all parts of a fluid or solid suspension of bacteria to identical conditions. And when we succeed we are met with the likelihood that the variation induced will only be transient. The very lability of constitution which with alteration of environment favours variation is apt to favour reversion to type when there is return to the original environment. Thus we have still to discover the laws—if they exist—governing the permanent alteration in the constitution of the bacterial protoplasm and production of permanent species instead of transient variants.

This book might well induce some young well-equipped bacteriologists to take as their central work the study of bacterial variability and of what constitutes a bacterial species.

THE OPERATIONS OF OBSTETRICS.

Embracing the Surgical Procedures and Management of the more Serious Complications. By FREDERICK ELMER LEAVITT, M.D., formerly Assistant Professor of Obstetrics and Gynæcology, University of Minnesota, &c. London: Henry Kimpton. 1919. With 248 illustrations. Pp. 466. 30*s*.

IN this work the author presents the subject of obstetrics from the operator's point of view, only enough pathology and physiology being introduced to give reason for and insight into the various procedures described. The indications given for pubiotomy are good and sound, and we notice that the author, even when such indications are present, thinks Cæsarean section generally the better operation. Hardly enough space is devoted to internal and external podalic version, and nothing is said of the great advantage of performing the major part of this operation by the abdomen. The section on version is, however, on the whole good, and the illustrations excellent. The chapter dealing with the midwifery forceps is also full and good, although we think the author might have laid more stress upon the many advantages of the axis-traction forceps. It is a pity that the term cranioclasis is used for the simple operation of delivering the perforated head by the cranio-tractor or craniotomy forceps, since this term in most books is definitely applied to the procedure of removing the vault of the skull. We cannot agree that craniotomy need not require more skill than a forceps delivery; a difficult craniotomy calls for a considerable amount of skill, and may be a very formidable and difficult operation. It is curious how many American authors seem to be unacquainted with Ramsbotham's decapitating hook, a much better and easier instrument to use than Braun's hook. In discussing the results of the operation of Cæsarean section no mention is made of the very valuable series of statistics collected by Amand Routh.

Dr. Leavitt apparently is not in favour of the now general treatment of rupture of the uterus by abdominal section, although this would seem to be the now recognised method; and when suitable means are taken to combat the shock, and with the more general use of spinal anæsthesia, this procedure would seem to hold out a prospect of giving good results in the future. The section on accidental hæmorrhage is disappointing, and we are surprised to find the author advocating accouchement forcé in view of the disastrous results obtained in this way. No mention is made of the good results obtained by plugging the vagina, as practised at the Rotunda Hospital; nor does the author appear to be acquainted with the excellent results following the Dublin method of treating eclampsia; nor that the method of non-intervention advocated by Stroganoff gives the best results of all—namely, a mortality of only some 6·6 per cent., as against the mortality of 13·5 per cent. among cases treated by rapid emptying of the uterus.

The book is an interesting one, and should prove useful to those for whom it is written.

REST AND SUGGESTION,

And other Therapeutic Measures in Nervous and Mental Diseases. Second edition. By FRANCIS X. DERCUM, M.D., Ph.D., Professor of Nervous and Mental Diseases in the Jefferson Medical College, Philadelphia, &c. London: Kegan Paul, Trench, Trübner, and Co. 1919. Pp. 395. 21*s*.

WE suppose most members of the profession in actual practice are conscious of a feeling of dissatisfaction in their methods of handling patients with functional nervous disease in any of its multiple forms. Conscious as he is of ever working against time, the busy man, if he is honest with himself, nevertheless hates to dismiss the functional case with a pat on the back and a prescription for a tonic. He has heard of the newer ways of treating such cases by year-long analysis or daily suggestion, but is only too well aware of his comparative ignorance of these therapeutic means, and he fears to step in. At the same time he is unwilling to send the neurotic patient away and the result is an unsatisfactory compromise benefiting neither. A little orientation in the practical principles of rational psychotherapeutics would materially aid him in his daily round. For that he might with advantage turn to Professor Dercum's volume, which lays emphasis on (1) purely medical treatment; (2) simple physiological methods, such as rest and feeding; and (3) the separation of the wheat from the chaff in the chaotic state of present-day psychotherapy. The hysteric, the neurasthenic, the psychasthenic, are dealt with individually along lines which any intelligent practitioner can readily follow, and on principles easily applicable to particular cases. A full consideration has also been given by Professor Dercum to "mind cure," "faith cure," Christian science, and mystic and religious methods generally, each procedure being subjected to a critical analysis.

We appreciate the therapeutic wisdom so amply revealed in the book and cordially commend it to the profession.

PSYCHOLOGY AND THE DAY'S WORK.

A Study in the Application of Psychology to Daily Life. By EDGAR JAMES SWIFT, Professor of Psychology and Education in Washington University, St. Louis. London: George Allen and Unwin, Ltd. 1919. Pp. 388. 10*s*. 6*d*.

WHY WE DO IT!

Psychological Gossip. By R. MCMILLAN. London: T. Werner Laurie, Ltd. 1919. Pp. 218. 6*s*.

THE art of popularising psychology has advanced much farther in America than in this country. Professor Swift is a scientist, and his style is that of a university lecturer; Mr. McMillan has also lived in the atmosphere of an American university, and has derived much of his wisdom from Hugo Munsterberg, though a life of travel and journalism has made a deeper impress on his writing. But both these authors have in their separate ways set out to accomplish the same task—to reveal to the uneducated in psychology what this science has to teach men about themselves. Professor Swift speaks of us as adapting ourselves by the method of "trial-and-error," and has some severe things to say about the small part which reason has played in the development of the science of medicine up to the beginning of the scientific period. "Systems of medicine—if the philosophical and religious view of diseases and their cures may be so dignified—followed one another as philosophy and religion changed. Medicine, like other beliefs, rested on authority. Systems were respectable or disreputable. Massaria of Padua, in the sixteenth century, would rather be wrong with Galen than right with any other physician. One system was used until another was thought to be better, though at that time the trial-and-error judgment was guided more by the underlying philosophical belief than by the results of the treatment." And although the scientific method of investigation and experiment is now with us the old trial-and-error method still continues "the chief method of modern man."

Mr. McMillan states the same case by concluding that we are automatous. His arguments are not convincing, except when they are taken from the mouths of his teachers, for his own mind is not always clear. He has grasped the fact that the word psychology "has a lot of meanings" (p. 135), but not with sufficient force to save himself from using it in two different senses on p. 19, when he attempts to define the word for his readers' benefit. But what his work lacks in definition it supplies in entertainment. Why do people throw an old slipper after a newly married couple? Why do people "touch wood" when they fear evil? Such are the problems which interest him, and in attempting the elucidation of such problems as these we learn that "when Rhadamanthus was King of Crete he passed a law that nobody should swear except by the dog, the goose, or the plane tree." How many of us knew this? Or that "amongst the laws that Hammurabi found in Babylon was one that if a man got drunk and did any damage the keeper of the wine-shop where he got intoxicated was held responsible"? This is not serious psychology perhaps, but it is not intended to be so.

LEHRBUCH DER AUGENHEILKUNDE.

Third edition. By Dr. PAUL RÖMER, Professor of Ophthalmology at the University of Greifswald. Berlin and Vienna: Urban and Schwarzenberg. 1919. With 297 illustrations and 32 coloured plates. Pp. 496. 30 marks.

THE author dedicates this edition of his text-book to the memory of his pupils who have fallen in the war, and states that he has abridged it as far as possible owing to the necessities created by the war. As compared with English text-books of similar size, it is fuller in some parts, as in the section dealing with phlyctenular disease, which is rightly treated as only one part of a general condition depending on defective nutrition; less full in others, as in the chapter on glaucoma, in which we miss any account of the early changes in the visual fields which are so important in diagnosis, while the operative treatment of the disease is dealt with in a manner quite inadequate to its importance.

The book is copiously illustrated in a way which will appeal to the student, while in some instances the illustrations are of value to the ophthalmologist. We may give as examples the coloured plates of blue punctate cataract, of the microscopic section of the choroid in sympathetic cyclitis, and of the ophthalmoscopic picture of colloid excrescences of the lamina vitrea. This last picture, by the way, appears twice, as do certain others of the figures in the coloured plates. Adaptation of illustration to text is not as exact as it should be; in the pictorial representations of the operation for cataract the corneal incision is shown far too large, as is also the iridectomy, although the description in the text is correct.

PRACTICAL PHYSIOLOGICAL CHEMISTRY.

For Indian Medical Students and Clinical Assistants. By C. C. CALEB, M.B., M.S. Durh., Professor of Physiology, King Edward Medical College, Lahore. London and Calcutta: Butterworth and Co. 1919. Pp. 252. Rs.6 net.

THE author states in his preface that his book is founded on his lecture notes, and that considerable use has been made of several other books on the subject. Consequently the book presents no essentially new features, and we can easily trace the parent books. The routine of most physiological laboratories is followed, but the author gives rather more than the usual space to the explanation of the various reactions and their physiological and medical significance. This is the best feature of the book, for the explanations are very clear, and must be of value to the student. Reference is rightly made to Indian foodstuffs. As the title indicates, the book is intended for Indian medical students, but it should prove useful to others. We are glad to see a copy of this book, for it shows how carefully Dr. Caleb has taught his students at the King Edward Medical College, Lahore, and we very much hope that a similar course is given in other Indian medical schools.

JOURNALS.

Science Progress. January, 1920. London: John Murray. 6*s.* quarterly.—The work of the late Dr. Charlton Bastian on the question of the possibility of the formation of living organisms from non-living matter is referred to in the January number of *Science Progress*, where there appears a short article by his son, Surgeon-Commander W. Bastian, R.N. In this he draws attention to the fact that in answer to his letter to THE LANCET in May last several letters appeared, but that few were from those who had done any experimental work along the lines laid down by Dr. Bastian, and he urges that a series of experiments should be undertaken on the exact lines described in Dr. Bastian's book, "The Origin of Life." The matter is well worth considering, for many of the objections to the reception of these ideas were based on theoretical reasons.

Maternity and Child Welfare.—The January number of this journal contains a cartoon the motto of which apparently embodies its policy for 1920—"Let's start fair." It contains the usual "20 minutes' talk to mothers," which this month explains lucidly and concisely the somewhat complex duties of the Minister of Health. An interesting account of the satisfactory results obtained by home subsidies, rest homes, and hostels in Liverpool is given by Dr. Ruby McBirnie. Miss Maud Higham writes pleasantly on "The Art of Story-telling," while Miss Jessie Allan deals fully with the subject of the mother in industry from the standpoint of a welfare worker, estimating both the value of the mother to the employer and the value of the employment to the mother. The Conference on Child Welfare in South Africa recently held in Durban is commented on editorially, and the opening address by Dr. Charles Porter, M.O.H. of Johannesburg, and a paper on "The Duties of a Health Visitor in South Africa" are quoted at greater length. The journal's French correspondent describes the municipal creche at Tours, the new maternity centre at Creusot (Saône et Loire), and discusses the secret lying-in hospital recently established at Lyons in connexion with the whole problem of secret confinements. Other features in an interesting issue are articles on women's institutes, the economics of child welfare, and the colony of Serb babies in Corsica.

American Journal of Ophthalmology. May to November, 1919.—Of several articles we select the following for comment.—May: Heydt Fundus Pathology with the Red Free Light of Vogt. A new method of ophthalmoscopy has been devised by means of a lamp with filter apparatus, giving a red free light. The greater part of the fundus looks blue with the vessels showing black, but the macular region is yellow. The nerve striations of the retina are rendered visible and changes in them can be detected in cases of retinitis and optic atrophy which are invisible by the ordinary method of examination. In albinos the yellow appearance of the macula is not seen, showing that this has a direct or indirect relation to the lack of pigment in general. It is claimed that the red free light affords the only objective method by which some cases of retro-bulbar neuritis can be diagnosed. The new method will probably have an important future, but it is one that requires to be learnt, even by the expert in ordinary ophthalmoscopy.——June: The article by H. H. Briggs on Hereditary Congenital Ptosis, with report of 64 cases conforming to the Mendelian rule of dominance, has already been noticed in these columns.[1]—A. B. Middleton contributes some interesting drawings (plain and coloured) of congenital conditions of the fundus found during the routine examination of 200,000 troops.—W. McLean writes on his new form of tonometer, which has excited considerable interest in this country, and J. N. Evans shows a test type suitable for young children.——The July number has several interesting articles. C. A. Clapp: Detachment of Retina in Eclampsia and Toxæmia of Pregnancy. Six cases were seen during a period of 18 months in a lying-in hospital at Baltimore. Full reports are given with illustrations, which show the detachments to have been in all cases very definite. Clapp is of opinion that if ophthalmoscopic examinations were generally made in these cases detachment would be discovered far more frequently than heretofore recorded. The prognosis is exceptionally good. In all his six cases reattachment took place with normal fields of vision.—F. A. Conlon: Conjunctivitis due to Food Anaphylaxis. "It has long been known that certain foods when eaten by individuals peculiarly sensitive or anaphylactic to these foods develop certain symptoms or ill-effects. Among the better known disturbances are urticaria, eczema, vaso-motor rhinitis, angio-neurotic œdema, and bronchial asthma." Conlon gives good evidence to show that conjunctivitis must be added to the list. In his cases strawberries, tomatoes, eggs, and flounders have been the culprits. To diagnose the offending foods he used the protein skin test devised by J. C. Walker, in his investigation of the cause of bronchial asthma, for details of which the original paper should be consulted.—R. P. Luna: Ocular Lesions consecutive to the Injections of Anti-typhoid Vaccine. There appears to be good evidence that anti-typhoid vaccination may be the occasion of certain eye troubles to which the patients have a predisposition or from which they have already suffered. The most typical of these appears to be herpes febriles corneæ, and there may be a similar relation to cases of irido-cyclitis. He concludes that it is not prudent to vaccinate luetic, tuberculous, and rheumatic subjects who have previously had lesions of the uveal tract.—Lloyd Mills: The Effects of Faulty Cranio-spinal Form and Alignment upon the Eyes. Severe ocular imbalance is found more commonly among cases which are primarily orthopædic than among average eye cases. In this article a connexion is traced between right- (or left) handedness and cranial asymmetry, spinal curvature, hyperphoria, and corneal astigmatism. The logical applications to preventive medicine are (*a*) that ambidexterity must be insisted on during the infantile period and the plastic developmental years, and (*b*) the importance of the early recognition of spinal defects and of their cure in youth by the orthopædic surgeon.——August: Dr. Duane's article on the Eyes of the Signalman has already been noticed.[2]—Allen Greenwood: The Organisation and Activities of the Ophthalmic Service in the American Expeditionary Forces. Detailed suggestions for the improvement of the service are made.——September: An Operation Relegating Enucleation of the Eye to its Proper Position. The operation described is a modified Mules's operation, the chief modification being that a window is cut in the back of the sclera, through which the optic nerve is divided. A channel for drainage being thus obtained, it is found that the gold ball inserted into the scleral pocket is not subsequently extruded.—Harvey J. Howard: A Test for the Judgment of Distance. This article has importance in relation to aviation. Of the several factors which contribute to the correct judgment of distance, some are independent of binocular vision, others are not. In comparing the relative ability of different individuals in this respect the factor of binocular parallax was found to be the most important. To test this an apparatus modified from one devised by Brooksbank James in 1908[3] is described.——October: Edward Jackson and W. C. Finnoff: Tuberculosis of the Retina. Interesting drawings of a case occurring in an adult are given.—John Green, jun.: Treatment of Dacryocystitis by Curettage Supplemented by Immediate Rapid Dilatation of the Lacrimonasal Duct. The periodical appearance of new methods of treatment for this trying condition indicate that no finality has yet been reached.—L. Webster Fox: A New Operation for the Relief of Conical Cornea. This consists in excising a portion of cornea and suturing the flaps. A special forceps is figured for holding each corneal flap while inserting the sutures.——November: A. B. Middleton: Macular Hole in the Retina.—E. E. Maxey: Hole at the Macula. These two papers are illustrated by several figures showing examples of this condition found in the one case during the routine examination of recruits for the U.S. army, in the other at a base hospital.—S. G. Higgins: Visual Disability from Eye Injury and Compensation. Certain questions were put by the Industrial Commission of Milwaukee to the Oto-Ophthalmic Society of that State, the answers to which will be of interest to those in this country concerned with the same problems. Compensation, they say, should vary with character of employment, and they publish a table suggesting that on the average useful vision is diminished by 3 per cent. for every 10 feet disability to read the Snellen chart, so that, for instance, vision of 20/40 would imply 94 per cent. ability, while 20/350 would imply 1 per cent.

[3] THE LANCET, 1908, i., 1763.

La Semana Medica, of Buenos Aires, for Dec. 4th, 1919, contains an article by Dr. Angel Bianchi Lischetti, professor of zoology and comparative anatomy and physiology at Buenos Aires, which may prove to have an important bearing on the question of malaria prevention. The article bears the title, "Un Verme del Genero Planaria, Enemigo Natural de las Larvas del Mosquito" (a worm of the genus Planaria, a natural enemy of mosquito larvæ), and describes a series of observations of extraordinary interest. Being desirous of accumulating a reserve of "plancton" to serve as food for mosquito larvæ whose biology he was studying, Professor Lischetti placed in a large glass vessel a quantity of water containing vegetable growth of various kinds and small animals, taken from the tanks in which aquatic plants were growing in the Botanic Garden of the Faculty of Agronomy and Veterinary Science at Buenos Aires. On examining this water he noticed that, though offering excellent conditions for the development of mosquito larvæ, it contained exceedingly few larvæ or nymphæ, many of the samples containing none at all. This was at first attributed to the presence of frogs and toads in the tanks. At the end of December, 1918, 30 larvæ of *Ædes Calopus*, four days old, were placed in the glass receiver with a view of obtaining adult larvæ. Two days afterwards on looking for the larvæ, which it was expected to find fully grown, no trace could be found of them. On Jan. 10th, 1919, a large number of eggs of *Ædes Calopus* were found on the sides of the receiver close to the water surface and among filamentous algæ. Daily watch was kept on the receiver in order to determine the date of appearance of the larvæ. None having appeared by the 18th, some of the eggs were examined microscopically and found to have undergone normal hatching. The complete disappearance of the larvæ in this case suggested the possible presence of some natural enemy to them, and it was decided to investigate the matter from that point of view. On Jan. 25th, at 4 P.M., 30 culex larvæ were placed in the receivers. The next day only three of these were found alive, and these had disappeared at 8 A.M. on the 27th, leaving behind only a few heads, some stigmatic tubes, and fragments of the chitinous covering—that is to say, the hardest parts of the animals' structure. A thorough examination was then made of the fauna and flora of the water in the receiver and, among other species, the constant presence was noted of a species of worm of the genus planaria. The fact that the larvæ, if small, disappeared entirely and, if larger, left behind only the hardest and most resistant parts of their anatomy, led to the inference that they had been devoured by the planaria, this being the only animal present large enough and active enough to be capable of the feat. On Feb. 28th six of the worms and ten culex larvæ were placed in a vessel full of drinking water. At 8 A.M. next day only three larvæ remained alive; the heads of four others were found, and by 7 P.M. the three that had survived the night were no more. In view of this result experiments were made with a view to determining the method and the rate of destruction wrought by the planaria. On March 5th six planaria individuals having been placed in a vessel containing 100 c.cm. of drinking water, batches of larvæ varying in numbers were introduced in succession into the vessel.

The following table shows what happened:—

4	P.M.			introduced	5	larvæ.	
4.10	,,	remained	2	,,	10	,,	
4.25	,,	,,	4	,,	22	,,	
4.50	,,	,,	3	,,	11	,,	
5.10	,,	,,	5	,,	16	,,	
6	,,	,,	7	,,	22	,,	
6.30	,,	,,	5	,,	9	,,	
6.45	,,	,,	3	,,	13	,,	(2 large).
8	,,	,,	2 (large)				
					108		

Six planaria individuals, therefore, disposed in four hours of 106 larvæ, the sole survivors being 2 large ones. Large larvæ were found throughout the experiments to withstand with comparative ease the attacks of the planaria. As it appeared probable that the destructive powers of the planaria would be diminished after an abundant ingestion of larvæ, the six were placed at 8.30 in a vessel containing 200 culex larvæ. Immediately on their introduction, however, the planaria commenced a hunt, the details of which were watched until 10 P.M. It was observed that after devouring several larvæ a planaria would remain at rest for some ten minutes and then renew the chase. Next morning most of the larvæ had disappeared, no normal larvæ could be seen, those that remained either adhering together in clumps or lying motionless at the bottom of the receiver. The following description is given of the method of attack adopted by the planariæ. They live under water, creeping about the sides of the receiver or close to the surface of the water. They reach the bottom of the receiver either by creeping down the sides or by letting themselves sink through the water by gravity. To reach the surface they always creep up the sides or up submerged objects. The presence of culex larvæ seems to cause a kind of excitement, for directly they are placed in a receiver containing planariæ, the latter begin to quarter the surface of the water in all directions, attaching themselves in an inverted position to the under surface of the pellicle formed by the surface tension of the liquid. The attack is delivered at the moment in which the larva, in order to breathe, applies its stigmatic tube to the surface of the water and remains for an instant immobile. If at this moment a planaria passes the spot it applies to the stigmatic tube one of the lateral lobules of its head, and the larva remains adhering thereto, owing to a viscid secretion which covers the body of the planaria, only well-developed larvæ being able, owing to their greater strength, to escape, which they do by a violent wriggling movement. In many cases, even when the larva has succeeded in tearing itself free, it is seen immediately to arch itself in an endeavour to remove with its mouth the matter adhering to its tube, when it frequently happens that mouth and tube remain glued together, and the larva, unable to move, falls to the bottom and dies asphyxiated. As soon as a planaria has succeeded in attaching itself to a larva it proceeds to twine itself round the latter's body by a helicoidal movement, the victim endeavouring by violent movements to free itself, but not succeeding. The planaria and larva, now leaving the surface, fall to the bottom of the receiver and the former places itself over the body of the latter, and immediately evaginates from its median ventral segment its retractile pharynx, inserts it between two segments of the larva and passes it interiorly along the whole length of the latter's body as a finger is passed into a glove. It is then withdrawn, bringing with it the whole internal economy of the larva and leaving nothing behind but its empty chitinous envelope. Often, and especially when the number of larvæ is small in relation to the number of planariæ, if one of the latter has made a capture, others hurry up and endeavour to carry off the victim. Adult larvæ and nymphæ almost always escape, the former owing to their strength, the latter to their agility. The interest and importance of Professor Lischetti's observations need no emphasis. So far, it would appear, only culex larvæ have been the subjects of his experiments. It is to be hoped that they will be repeated as early as possible with larvæ of anopheles.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 7, 1920.

The Insurance Practice Settlement.

THE Ministry of Health has announced the names of the three gentlemen who have consented to act as arbitrators on the question of remuneration at issue between the Government and the medical profession, as laid before them by the assessors. The arbitrators are Mr. F. GORE-BROWNE, K.C., a Master of the Bench of the Inner Temple; Sir RICHARD VASSAR-SMITH, President of the Council of the Institute of Bankers and chairman of Lloyd's Bank; and Mr. J. C. STAMP, D.Sc., secretary to Explosives Trades, Ltd., and a member of the Royal Commission on Income Tax. Mr. GORE-BROWNE is to act as chairman. The exact terms of reference are:—

> To advise the Government what should be the amount of the capitation fee (per insured person per annum) on the basis of which the Central Practitioners' Fund under Article 19 (i.) of the Medical Benefit Regulations, 1920, should be calculated, so as to afford fair remuneration for the time and services required to be given by general practitioners, under the conditions set out in those Regulations, in connexion with the medical attendance and treatment of insured persons.
>
> This capitation fee is not to include any payment in respect of the supply of drugs and appliances (such payments being met out of the Drug Fund under Article 22), nor any payments to meet those special conditions of practice in rural and semi-rural areas which are covered by the payments to be made out of the Central Mileage Fund under Article 19 (ii.).

It was understood that the award was to be completed within four weeks, although we may well hope that agreement will be reached even sooner on an issue in which the materials for decision lie to hand.

The arbitration will, we may presume, settle the basis of remuneration for the time being; for although there are a number of practitioners in various parts of the country who are honestly satisfied that it is not for them to offer willing service on less than such-and-such a capitation fee, there is a very general desire to assist the Ministry of Health in administering medical benefit under the Insurance Acts at a difficult transitional period. The vital matter, in the minds of many, the good-will of panel practice, is not alluded to in the terms of reference. The action of the Cheshire Local Medical and Panel Committee illustrates how keenly this question is felt. At a meeting of this body, held at Crewe a fortnight ago, it was announced that agreement had been reached with the Cheshire Insurance Committee on the method of transferring a medical practice on the death of a panel doctor. This agreement requires the approval of the Minister of Health, and the Cheshire Panel Committee has resolved, failing the ratification of the agreement, to advise its constituents to decline service under the Insurance Acts. Cheshire doctors agree with their colleagues elsewhere that patients should have the opportunity for free choice, but they consider that, where choice is not exercised, patients should be allotted automatically to the successor of a deceased doctor, in so far as they do not lie outside his ordinary radius of practice. A similar clause was recommended by the Insurance Acts Committee of the British Medical Association to all Panel Committees, but the disapproval of the Ministry was signified in a circular letter issued on Jan. 19th. The objection of the Ministry was expressed in the following passage:—

> The Allocation Sub-committee, within their discretion may, of course, lay down general lines of procedure which they will in practice follow so far [illegible] they can consistently do so, having regard to the merits of the particular cases before them, and it is not desirable that their hands should be tied in advance in regard to the assignment of insured persons.

The objections, from the public point of view, of creating vested interests have prevailed.

Rules and regulations are necessary in any public service. They are the only means whereby a Government Department is able to maintain a standard of duty guaranteed by the Act of Parliament under which any service is instituted. But while regulations may cajole the wayward and keep up a show of energy in the slacker, they are often a source of chagrin and sometimes a positive drawback to the honest work of the conscientious man. Dr. ADDISON frankly recognised this, when faced by the deputation from the British Federation of Medical and Allied Sciences, which asked for a public inquiry into the whole working of medical benefit. The Panel Committees had, he reminded the deputation, given an undertaking through their representatives that a satisfactory service would be given in return for increased remuneration. Should any regulation prevent a practitioner from giving of his best, the Minister agreed to remove the restriction forthwith. That assurance may do for the present. Insurance practitioners demand no favoured position. Their standard of conduct is that of the rest of the medical profession, and the svere judgments which they pass upon the conduct of their colleagues are often a source of amazement to the Medical Service Subcommittees before which complaints against panel practitioners are lodged. What Insurance practitioners chiefly desire is to have elbow-room, in discharge of their duties towards their panel patients, wherein to practise their art without irksome supervision. Dr. ADDISON, we believe, admits this.

Symptomatic or Partial Diagnosis.

In a review published in The Lancet of Jan. 17th (p. 158) there occurs the terse dictum: "No man should be pensioned for D.A.H." This is a conclusion arrived at by Captain R. M. Wilson and Captain W. M. T. Wilson after an analysis of the various conditions lumped together under this vague and unsatisfactory grouping. The term "disordered action of the heart" does indeed occur in the 1918 edition of the official Nomenclature of Diseases to cover conditions as various as tachycardia, Adams-Stokes's disease, and Graves's disease, but a footnote is added to the effect that when the cause is known, return should be made under the head of such cause, the local condition being also specified. "D.A.H.," that is, should not be employed except as a temporary classification under conditions of active service to assist in evacuation and distribution. We have in essence a plea for accurate diagnosis. By a coincidence the same number of The Lancet contains a letter from Sir Thomas Horder referring to a well-known definition of medicine, attributed in its original form to more than one leader of our science—it runs, "Medicine has three parts: the first is diagnosis; the second is diagnosis; and the third is diagnosis." In this connexion we may repeat Dr. W. H. R. Rivers's definition of diagnosis which seems to us complete, and which led to Sir Thomas Horder's letter. Dr. Rivers says: "The word connotes the whole process by means of which we come to understand the nature of each individual case of disease, and analyse into its elements the complex web of agencies by which the morbid state has been produced." This covers the ground, and puts nomenclature into its right place as a convention necessary for the intercommunication of ideas.

In military medicine convenience, and perhaps necessity, have sanctioned the use of abbreviations or initials such as D.A.H., V.D.H., N.Y.D., and P.U.O. Written at length their insufficiency or even absurdity becomes apparent, but may we not ask whether many practitioners, who scoff at the obvious weakness of these abbreviations, do not often rest satisfied with equally incomplete tentative or deceptive terms, and fail to achieve a real diagnosis, when with further analysis or investigation such a diagnosis may be possible? Disease should be regarded as a dynamic rather than a static condition, and diagnosis should involve a recognition of the process rather than a mere statement of the resultant condition or its symptomatic expression. Too often diagnosis is incomplete because the observer rests content with the recognition of a symptom or a symptom-complex which may be common to many morbid processes. Jaundice, dyspepsia, D.A.H., and constipation are gross examples, which are only too apparent and can be indefinitely multiplied, but there are more complex and more subtle instances which are less obvious and therefore more dangerous. The labelling of all cases of arterial thickening as arteriosclerosis without qualification tends to render treatment of these conditions haphazard. The application of the useful term fibrositis to all and sundry pains in connective tissues may lead to ineffective treatment, or, worse, to disaster from the non-recognition of grave morbid conditions underlying the particular symptom. The terms functional disease, hysteria, and neurasthenia are frequently responsible for the failure to recognise serious organic disease hiding behind the functional exaggerations or mimicry of a fatigued, poisoned, or over-active nervous system. It is the morbid process in disease with which diagnosis is concerned, and scientific diagnosis is really an "insight" into disease.

It is sometimes useful for a medical man in charge of a difficult or a prolonged case to review his diagnosis, and, as it were, to look at the patient as a new case. Mistakes not infrequently occur from overlooking the obvious, from failing to notice some change in the patient or his physical signs, owing to the too ready acceptance of a tentative or partial diagnosis made in the early stages of an illness. A later observer, examining the case, takes a larger view, and with a more accurate perspective arrives at a correct diagnosis. The original observer, when it becomes clear that he has not arrived at the fundamentals, should hasten to put himself into this critical attitude. In the review to which we have referred, this question of accurate diagnosis is primarily considered from the point of view of the assessment of pensions—that is to say, from the standpoint of prognosis. But accurate diagnosis is essential for the effective treatment necessary to establish the forecast. Treatment has of necessity to be symptomatic or palliative where disease is advanced and incurable, or in cases where no specific or fundamental treatment is yet available, but the medical man who is satisfied to treat symptoms without first probing to the full after accurate diagnosis is not even a craftsman—much less the man of science he should strive to be.

Epidemic Dropsy.

"The triple scourge of war, pestilence, and famine disgraced the reign of Justinian," says Gibbon, and frequent repetition in history shows that their association is not fortuitous. As Dr. Douglas Bigland said in his interesting paper on œdema in food-deficiency diseases published in our columns last week, "Whenever there are wars, famines, and long voyages in ill-equipped ships; wherever persons are housed together under relatively bad conditions, as in asylums and prisons; wherever the population lives on a minimal or one-sided dietary, liable at times to be reduced to a fraction above nothing, there we have the conditions for the development of food-deficiency diseases and there we have epidemic dropsy." His paper and that of Dr. J. I. Enright, which we publish to-day, raise the question of the mechanism of the production of œdema by food deficiency and its relation to other recognised forms of dropsy. The appearance of epidemic dropsy in war is no new thing. It was observed in the American Civil War, but before long this was traced to nephritis. Similarly, when epidemic nephritis first appeared in Flanders in 1915, it was first recognised as epidemic dropsy. But these epidemics occurred in troops who were still well nourished and well fed, and were, therefore, quite different from the isolated outbreaks in India and Mauritius, and from those recently observed among Turkish prisoners of war and among the native troops in East Africa. After studying the Calcutta outbreak of 1908–09, Greig concluded that it was a nutritional disease, brought about by one-sided dietary. All the deficiency diseases are apt to present dropsy. Pellagra has been shown by Boyd and others to be due to the insufficiency of "biological" protein, which we take to mean the protein actually assimilated. Beri-beri and scurvy are both recognised to be deficiency diseases. Any disease which leads to blood destruction, such as malaria or ankylostomiasis, appears to help the production of epidemic dropsy, but in Dr. Bigland's opinion blood destruction is not adequate as a sole cause. Dysentery is often associated with epidemic dropsy partly because both diseases are common under conditions of food shortage, but also because dysentery means that such food as can be given is inadequately assimilated. The Lunacy Commissioners regarded the alarming increase of sickness occurring in the asylums of England and Wales during the years 1917–18 as due in the main to food deficiency, and the letter of Dr. W. F. Menzies in our correspondence columns sets out, from his own observation, the part which hunger œdema played in this increase.

A good case can, therefore, be made out for deficiency of vitamines as a cause of dropsy. We may next inquire as to the mechanism by which it is brought about. McCarrison has put forward the theory that the œdema of inanition and beri-beri is initiated by the increased intracapillary pressure which results from increased production of adrenalin, acting in association with malnutrition of the tissues. It is not clear how adrenalin would effect this, since the constriction of the arterioles produced would tend to shut off pressure from the capillaries. Dilatation of capillaries has been produced by minimal doses of adrenalin, it is true, but not by an increase over the normal amount in the circulation. C. Bolton's experimental production of œdema in animals is pertinent to the discussion. He tied off a portion of the pericardial sac so that the residue of the pericardium was too small for the heart, thus preventing its free expansion. This interference with its diastole caused distension of the great veins and then dropsy. Observations of the arterial and venous blood pressures did not suggest that a rise of capillary pressure was responsible for this. Bolton concluded that it was due to the increased permeability of the capillaries, brought about by deficient oxygenation of the blood and impaired nutrition of the capillary wall. We are still too apt to look upon the capillary endothelium as a mere passive membrane, through which filtration occurs. Yet it has been shown to have a great resisting and selective power as long as it is well nourished. An endothelium, such as Descemet's membrane, can withstand a high filtration pressure as long as it is alive, but rapidly swells up under such pressure if it is killed. Mott showed that the cerebral hæmorrhages which sometimes occur a few days after carbon monoxide poisoning are due to fatty degeneration in the capillary endothelium of the cerebral vessels. The carbon monoxide takes up so much of the hæmoglobin that there is not enough left to carry oxygen to the tissue cells. That the capillary endothelium should suffer so markedly shows how dependent it is on oxygen for its maintenance. Dale and Richards's histamine experiments point in the same direction. Again, temporary ligature of renal vessels is followed by albuminuria. The capillary endothelium is, in fact, intensely sensitive to changes in oxygen-supply, nutritive defects, and to toxins. The influence of toxins in renal dropsy is clearly shown by the fact that it occurs where the activity of the renal tubules is diminished, as in parenchymatous nephritis, and not in interstitial nephritis, even though the blood pressure be high.

In deficiency disease, where many tissues show damage, it is not surprising that the malnutrition should affect the delicate structure of the capillary endothelium, and that the resulting damage should express itself as undue permeability. This does not exclude an influence of the vaso-motor nerves. The famine dropsies of India presented paræsthesia and deep-seated pains as early symptoms, showing that the nerves were involved; while neuritis is the most prominent symptom in beri-beri. As to pellagra, Roaf in this country and Dr. Mary Morse in America have demonstrated structural changes in the sympathetic nervous system, and the associated eruption is probably due to the vaso-dilatation resulting from this, since the vaso-constrictors, being sympathetic in origin, would be damaged. Adrenalin defect would act in the same direction as impaired sympathetic tone, and might therefore be a factor, though adrenalin excess could hardly do so, in our opinion. But damage to the capillary endothelium seems the simplest and most generally applicable explanation of dropsy, whether in anæmia, heart disease, renal disease, or in failure of nutrition due to lack of vitamines.

His Majesty's Stationery Office regret that, the orders for Sir George Newman's Report on Preventive Medicine being so numerous, they have been unable to despatch copies as quickly as they would have wished. All orders are being dealt with as promptly as possible in rotation, and as supplies are received from the printers. It is not anticipated that there will be more than a few days' delay.

Annotations.

"Ne quid nimis."

DENTAL SEPSIS.

THE importance of dental sepsis in lowering the standard of national health is becoming generally realised. The subject was discussed at the Section of Odontology of the Royal Society of Medicine on Jan. 26th, when Mr. F. St. J. Steadman read a paper on Dental Sepsis in Children: Its Consequences and Treatment, which we give in full in another part of our present issue. Dentists, as a body, know the danger of an unclean mouth, but they feel, and say, that the family practitioner often does not take the matter with sufficient seriousness. The practitioner is probably aware of the dental condition of his patients, but does not make opportunity to study the problems. As a result of recruiting, however, figures are available which must carry conviction to all. The Departmental Committee on the Dentists Act obtained information on the state of the teeth of recruits joining the army during the war. In the Scottish Command it was stated that "recruits from industrial areas and of the artisan and labouring class show little or no evidence of having had any attention paid to their teeth previous to enlistment, and almost every man requires dental treatment." It was estimated that 44 per cent. of the men were dentally unfit in a military sense—i.e., they lacked the minimum of dental efficiency which would ensure effective mastication of food. In the Aldershot Command, out of 35,645 men examined 72·2 per cent. required dental treatment, of whom 10·9 per cent. wanted extensive treatment and dentures. There were needed 37,483 extractions, 42,974 fillings, and 4985 dentures. In the London Command about 70 per cent. required dental treatment; of these, 40 per cent. required extensive treatment extending over several visits, whilst 38 per cent. required treatment for a month or more, with many extractions and provision of dentures. In the Eastern Command 83 per cent. of recruits of 18 and 19 years of age required treatment, and 93 per cent. of those between the ages of 19 and 44. In the Eastern Command 97 per cent. exhibited dental defects, 75 per cent. of whom were in urgent need of treatment. So much for the condition of the male population. With regard to the women, it is said that:—

> "The evidence submitted to the Committee indicated that the condition of the teeth of the women of the nation is worse than that of the men. Having regard to the direct connexion between defective dentition and ill-health, a greater amount of sickness would naturally be expected in respect of women than of men. The results revealed by the working of the National Insurance Act are in accordance with this expectation."

There is no need to enumerate the various affections which result from dental sepsis, either directly or indirectly, but as an instance of the prevalence of disease attributable to defective teeth we may recall the report which was submitted to the Army Council by the Southern Command. Of 304 medical cases examined 160 were suffering from troubles directly attributed to defective teeth, and from 60 to 70 from troubles indirectly so attributed. As is very forcibly pointed out in Mr. Steadman's paper and in the discussion which followed (see p. 324), there are not nearly sufficient dentists to carry out the work which should be done, but the provision made for the adult among the poorer classes is even less than that made for the school child. It is very unfortunate that what is not only desirable but absolutely necessary is rendered impracticable by the dearth of registered dentists.

MINERS' NYSTAGMUS.

THE economic aspect of miners' nystagmus was the subject of a paper recently read before the North Staffordshire Institute of Mining Engineers by Dr. T. Lister Llewellyn. Although in times past the disease was attributed to the constrained position of the body and eyes necessitated by the miners' work, it is now generally recognised that the most important element in its causation is defective lighting of the mines. The disease was, in fact, unknown previously to 1850, when the safety lamp was introduced, and its incidence appears to vary more or less inversely as the brightness of the illuminant employed in any particular mine. Physiologically, the mechanism of vision is different in a dim light from what it is in a bright one. The importance of the fovea centralis no longer exists, and vision is actually better some 15° or 20° away from it, where the retinal rods, instead of being absent as they are at the fovea, are at a maximum. Another factor in the causation of nystagmus is the crystalline surface of the coal face, which reflects light from innumerable facets, the one that happens to reflect most light into one eye being different from the one that reflects most light into the other. Yet another factor is probably some instability in the cerebral centres which regulate the reflex action of the eye muscles. An insufficiently understood fact is that the physical sign may persist for a long time without causing any symptoms, but any slight accident, or even the mere suggestion due to a medical examination in which the unconscious subject of nystagmus is told of his defect, may give rise to marked subjective symptoms.

The disease is one of deliberate onset, the average number of years of underground life before failure being 25 according to Dr. Llewellyn. It follows that the full benefit of any remedial measures will only gradually become apparent. The most important remedial measure called for is not in any manner of doubt—it is to devise a better illuminant for the safe lighting of mines. Dr. J. S. Haldane, in supporting Dr. Llewellyn's plea for better lighting, states that in American mines an electric light is carried on the cap or on the body in front, and connected by a cable to the accumulator carried on a belt behind, and that this method appears to solve the problem satisfactorily. If this is so, the £100,000 called for by Dr. Llewellyn to endow a research for a better illuminant for safe lighting would seem superfluous. In any case, since the loss to the State owing to this disease alone is estimated at no less than a million a year, it is plain that some action is urgently required. The discussion on Dr. Llewellyn's paper elicited an interesting fact. Mr. Caleb Johnson stated that six years ago electric lamps were installed in one of two pits working the same seams—at the same depth and by the same method. "As the result of six years' working these were the results obtained. In the pit where electric lamps were used 50 per cent. of the workings were lighted by electric lamps, about 70 to 75 per cent. of the men at the face having electric lamps. In that pit the cost of nystagmus was something less than one-thousandth part of a penny per ton of output. In the other pit, where oil lamps were still used, the cost of nystagmus was about three-fifths of a penny per ton of output." Again, as to accidents: "In the colliery where they had electric lamps he found that for every 53 shifts that had been worked one had been lost through accident. In the oil-lamp pit, for every 22 shifts worked one had been lost through accident. Further, the output per shift per person had been greater in the electrically-lit pit than in the oil-lamp pit." Another speaker raised the question of how far nystagmus may be due to other causes besides defective lighting in the pits. Congenital nystagmus and nystagmus from blindness in infancy, as well as from other causes, are well known, but this does not affect the fact that so far as the disease is due to the miners' vocation defective illumination is the prime factor in its causation.

VOLUMETRIC TESTS ON SCIENTIFIC GLASSWARE.

THE new facilities in regard to the standardisation of laboratory glassware recently announced by the authorities of the National Physical Laboratory, Teddington, deserve the attention of all those engaged in scientific work. We need hardly remind our readers that the manufacture of volumetric scientific glassware is an industry which was practically non-existent in this country before the war. It has since developed satisfactorily, and the high position it has gained should never be lost. The essential point is accuracy of measurement or calibration, and in this matter the authorities at Teddington are giving British manufacturers every possible assistance in undertaking for quite modest charges the work of standardising the apparatus they make. Scientific work is clearly advanced when the instruments employed in it can be obtained with a hall mark verifying measurements. The following paragraph, taken from the *Economic Review* (Jan. 21st), is interesting in this connexion:—

> *Faulty German Thermometers.*
>
> The *Chemiken Zeitung* (Dec. 30th) calls attention to the complaints current in Holland and Switzerland concerning German clinical thermometers, some of which are said to be useless. Although provided with a "test certificate," these thermometers have proved quite unreliable, errors of as much as 0·5 to 1°C. being registered. The *C. Z.* urges that measures should be taken to maintain the reputation of German manufactures.

These are just the measures which our National Physical Laboratory at Teddington is taking to maintain the reputation of British manufactures.

THE INDEPENDENT LIFE OF TISSUES.

IT IS now a commonplace of thought among the better-educated part of the community that the bodies of animals consist of masses of cells, differentiated structurally and functionally to serve the purposes of the general mass, whose individuality is the summation of the characteristics and activities of all the individual cells. This conception of the complicated structure of animals finds in recent years its most striking confirmation in the fascinating work of Ross Harrison, Burrows, Carrel, and numerous other American investigators on the cultivation of tissues in vitro. The conditions which determine whether a cell can live in artificial culture are similar to those which the body naturally provides. An adequate supply of appropriate foodstuffs, oxygen for the processes of combustion, removal of carbon dioxide and other waste products, and, what is now more clearly realised as an indispensable condition of cell growth and activity, a scaffolding or supporting framework. The provision of all these conditions for a cell outside the body is exceedingly difficult and represents a technical accomplishment upon which the American scientists have earned universal congratulations. The extent of the success which has already been achieved is shown by a contribution to the *Journal of Experimental Medicine* for December, 1919, in which Dr. A. H. Ebeling gives an account of his work in maintaining in culture a piece of connective tissue which was isolated by Dr. Alexis Carrel from a fragment of heart taken from a seven-day old chick embryo in January, 1912. This tissue has now been kept in cultivation outside the body for a period of over eight years, undergoing during the last seven years 1390 passages. The cultivation of animal tissues can in some respects, therefore, be compared to the work of the bacteriologist who keeps alive in artificial media species of bacteria which are never found outside the body. The difficulties are greater, but the principle is the same. It is still rather an astonishing thing to regard the cells of the heart as individuals which may be transplanted from day to day in artificial media and maintained in what may be called a condition of robust health. From these results it would appear that we are justified in looking upon the cells of animals as potentially immortal. Their death in nature is dependent upon accidents to the complicated mechanism of which they form a part. If the manner in which these accidents occur were completely known, and could be avoided, the individual cells would certainly go on living and performing their function for periods far greater than are customarily assigned as the limits of life to the species. The principal aim of medical science is to discover the mode in which the apparatus of the vast colonies of cells is disintegrated; and, given any measure of success in this, the work of Carrel and his colleagues affords grounds for the hope of immensely prolonging the life of man.

THE MEDICAL REPORT AS POPULAR EDUCATOR.

THE vast difference in educative value between the reports of various medical officers of health, to which we devoted a leading article in THE LANCET of Jan. 3rd, was seen to depend largely on the trouble taken to summarise the figures in readable form for the benefit of the lay public, and to make appropriate deductions therefrom. It was emphasised then that neglect to do this was more often a question of pressure of work than of unwillingness to trouble to make an annual survey of the local position in public health. Moreover, some medical officers maintain that the correct interpretation of vital statistics is an intricate and difficult task best left to the biometrician, and that their own function is confined to the accurate presentation of facts. A Memorandum (No. 9/Med.) just issued by the Ministry of Health deals with the contents and arrangement of the annual reports of medical officers of health for 1919, and should be of the utmost help towards their compilation. Directions are given as to the scope and type of information desired under the various main headings, which include natural and social conditions of the district, sanitary circumstance of the district, food, prevalence of and control over infectious diseases, maternity and child welfare, sanitary administration, other services, and housing. The portion of the report on housing is, on this occasion, to be bound separately in order to facilitate its perusal both locally and in the Housing Department of the Ministry of Health, but this fact is to be indicated in the relevant portion of the main report and detailed references inserted. If all medical officers of health adopt the official plan, and treat the subjects in the order indicated in the Memorandum, comparison of reports from different areas will be easy and experience can be pooled.

In a covering letter the secretary to the Ministry of Health dwells on the importance of these comparisons and the impotence of isolated effort. He emphasises the necessity of local distribution and publicity to engender popular interest and enlighten public opinion. An increase of public knowledge and interest in these matters, it is suggested, may also become an effective means of educating the citizens in the more important conditions of public health, of warning them against particular dangers, and of securing that highly important coöperation and confidence between them and the health authority and its staff which is essential to successful health administration.

THE NEW REGULATIONS FOR MEDICAL BENEFIT.

WE understand that a letter has been sent to all Members of Parliament by the Federation of Medical and Allied Societies, begging them to support a demand for an inquiry into the regulations under which medical benefit is obtained through panel practice, before any expansion or alterations in the provisions of the Insurance Act are proposed. This action of the Federation arises out of the reply given by Dr. Addison to the deputation which he received a few days ago, when he promised that he would unhesitatingly recommend such an inquiry, after receiving a report from the Medical Consultative Council, should he thus become convinced of the advantage to be derived. The Federation will be in a stronger position to criticise any existent or intended methods when the Medical Consultative Council have spoken; but they desire to keep before Parliament the urgency of the questions involved.

THE SMALL-POX MENACE.

WE have had occasion during the past two years to direct the attention of our readers[1] to the danger arising from the importation of small-pox infection from abroad, particularly in connexion with the return of our sailors and soldiers from parts of the world where the disease has been prevalent, or even severely epidemic. During 1917 only 7 cases of small-pox were notified in England and Wales; in 1918 the number increased to 51 in the urban and rural districts, along with 12 others in port sanitary districts, making a total of 63 cases for the year. But in the first half of 1919, according to an interesting contribution by Dr. R. J. Reece, published in the forty-eighth and last annual report of the Medical Department of the Local Government Board, there were no fewer than 179 notifications of small-pox in the urban and rural districts of England and Wales, as well as 29 others at our ports, making in all 208 small-pox cases in England and Wales during a period of six months. It is worth noting that a number of the local outbreaks in the first half of 1919 were traced to infection brought by soldiers returning from infected countries, such as Italy, Greece, and Egypt, while other groups of cases owed their origin to infection brought home by civilians or sailors from foreign ports in Spain or Portugal. The occurrence of severe epidemics of small-pox after great wars is a fact well recognised by epidemiologists. If it had not been for the care exercised at our ports in recent years the infection introduced from abroad would have led to a far greater prevalence, if not an actual epidemic, of the disease in our country. There is also no doubt, as Dr. Reece points out, that the prompt notification of cases, the speedy isolation of the patients, and the diligent inquiry made as to contacts all contributed to the successful prevention of the spread of the infection. Such measures, alone, however, cannot be implicitly trusted when small-pox invades an unvaccinated community. The long-continued absence of epidemic small-pox from our land has given rise, in many persons, to a false sense of security, and in consequence vaccination and revaccination have been neglected. In this connexion Dr. Reece mentions in his report that small-pox was contracted by some persons who had been in contact with patients, and who had refused the timely offers of vaccination or revaccination; there were instances also where even doctors, nurses, or members of the staff of the local sanitary authorities fell ill of small-pox, having trusted too much to their primary infantile vaccination, instead of seeking revaccination at adult age. A considerable proportion of our adult male population, who have been on military service, have been revaccinated, and are therefore protected (though, unfortunately, not all who went to the front were revaccinated); but, on the other hand, the vaccination of infants has been growing less and less of late years. Dr. Reece estimates that at present about half of the children of England and Wales under 10 years of age are unvaccinated. In pre-vaccination times the mortality from small-pox was greatest in those under 10 years, the majority of the deaths being children under 5 years of age. Should small-pox again become epidemic in our country we may witness a return to the old state of things and see many children die of small-pox whose lives could have been saved if their parents had accepted the opportunities afforded to them by the State for infantile vaccination.

THE FRANKNESS OF THE PHYSICIAN.

SOME few weeks ago Mr. C. E. Montague gave an address to the members of the English Association at Manchester University upon clearness in imaginative writing, and came to the conclusion that too much clearness was to be deprecated. "Every urbane writer, even when greatly explicit, would stop short of expounding the last detail of his meaning. ...... The best of imaginative writing has its leaves in the light and its roots in the darkness. ...... It is more blessed for a reader to guess right than to be told." Most of us will agree with Mr. Montague so far as literature goes, but the leaving of the reader to guess the writer's meaning produces in many instances extraordinary results. For instance, there is perhaps no one line of poetry in any language which has been more quoted, more discussed, and more misunderstood than—

---

[1] Vide THE LANCET, August 17th, 1918; and August 23rd, 1919.

"Sunt lacrymae rerum et mentem mortalia tangunt."

and all kinds of meanings and undercurrents of feeling have been read into this line, varying according to the taste and fancies of the readers. But, as shown by a writer in the *Classical Review* (February–March, 1919), all the presumed difficulty has arisen from the line being divorced from its context, and if taken in connexion with the accompanying lines its meaning stands out perfectly clearly. Here the guesses of readers have led them into a morass, but if Virgil had written a baldly clear statement much of the charm of the passage would have been lost. If we pass to the question of too much clearness in other departments of life we are met by the problem, "How far is it desirable to tell the whole truth?"—and this is a problem the solution of which very often affects the medical profession. Dr. Batty Shaw, in a paper which appeared in our issue of Jan. 24th, laid stress upon the fact that "probably all children ...... living under the conditions of civilisation are infected by *B. tuberculosis*." Further on he said, "I think that the subject of tuberculosis has become popularised too much, or should I say has been only partially popularised. It is more palatable to a lay audience to listen to the accounts of the marvellous cures which have come as a result of this, that, or the other treatment. It is not at all palatable, and lay men and women would not be tempted to join associations for the study of this disease if they were told the whole truth." Here, then, is one instance where the problem above mentioned comes forward for solution. If the average layman knew the whole truth, would it make him throw up the sponge in the contest against tuberculosis or would it stimulate him to further exertions? In this case the knowledge or reverse of the truth affects the community as a whole, but the same problem arises as affecting individuals in those many cases which arise in medical practice where it becomes the medical man's duty to decide whether or no he should tell his patient, or those responsible for the patient, the whole truth as to the disease from which that patient may be suffering. Hope, as everyone knows, is a large factor in recovery, and to dash such hope to the ground may be the last impulse which sends the sufferer into the abyss. But, on the other hand, there are cases in which, so far as human knowledge can tell, the patient is absolutely doomed; what should be the medical man's action then? In our opinion there can be no hard-and-fast rules for action laid down, for so much depends upon the individual circumstances of each case. May there not be too much clearness? Sometimes, surely, to paraphrase Mr. Montague's words, "It is more blessed for a patient to guess right than to be told."

INFLUENZA: PREPARATIONS IN SCOTLAND.

CORRESPONDING to the advice given by the Ministry of Health to medical officers and local authorities in England and Wales, a circular on the risk of a general outbreak of influenza has been issued by the Scottish Board of Health to authorities and officers in Scotland. The circular emphasises the importance of having in readiness a preconcerted scheme to meet the outbreak if it should come. The scheme recommended by the Board, subject to modification to meet local conditions, is as follows.

1. The local authority should appoint a small emergency committee to whom, with the medical officer of health, would be delegated full powers to act and incur necessary expenditure.
2. Medical practitioners and voluntary health workers should be consulted and their coöperation invited. The coöperation of the local employment exchanges of the Ministry of Labour should be invited also, in order that the opportunities for service may be brought under the notice of suitable persons.
3. A scheme should be drawn up for the provision of medical nursing and other assistance to the sick, and for the employment of women as home helps in cooking, care of children, and domestic work.
4. Arrangements should be made by which health visitors and other members of the staff of the local authority and of its institutions may be used to the best advantage and temporary creches and special kitchens promoted. The prophylactic inoculation of the staff of the health department and of nurses, home helps, and other workers under the scheme may be taken into consideration.
5. Wards of the infectious diseases hospitals of the local authority and of general hospitals should be set aside for the treatment of cases of influenza judged to require hospital treatment and the provision of emergency hospital accommodation should be arranged for in case of need.
6. Steps should be taken by the local authority to prevent overcrowding and to secure adequate ventilation in public buildings and public conveyances.
7. Notices and leaflets should be prepared for issue to the people having reference to the importance of free ventilation; the avoidance of needless exposure to infection; the necessity to keep away from places of public resort; and similar points; and furnishing for public information suitable details of the local authority's scheme.

The Board is prepared to supply gratis to medical officers of health, for distribution to practitioners and hospitals in their areas, supplies of recently produced vaccines against secondary infections. These are not intended to replace any other vaccine, prepared from a local strain, which may be in use in different localities.

RUPTURE OF AN AORTIC ANEURYSM INTO THE LEFT INNOMINATE VEIN.

RUPTURE of an aortic aneurysm into the superior vena cava is so rare as to be among the curiosities of medical literature. Dr. J. B. Herrick has recently reported[1] a case of rupture into the left innominate vein within less than a third of an inch from its debouch into the cava, which can therefore be classed under the same head.

The patient, a medical practitioner, aged 33 years, had suffered for 6 months from pains in the chest which at times extended to the right arm. He denied syphilis, but the Wassermann reaction was strongly positive. One evening while ascending stairs he had a feeling of something giving way in his chest, and his face and neck felt flushed and full. The sense of choking and pressure was so urgent that he tore open his collar and the neckband of his shirt. While trying to turn on the electric light he lost consciousness. How long he lay on the floor in a swoon was not known—he thought about 20 minutes. On recovering he turned on the light and looked in the mirror, and saw that his neck and face were swollen and "almost black." Breathing was difficult and he summoned aid by telephone. During the next five weeks he suffered from dyspnœa, at times amounting to orthopnœa. Attacks of coughing, with choking sensations and cyanosis, seemed to threaten death. He became weak and irritable, and at times was somewhat delirious. At the end of this period he came under Dr. Herrick's observation. The picture was such as he had never seen before. The face and neck, as well as the chest wall, were swollen, as in the anasarca of chronic parenchymatous nephritis. The injected eyeballs bulged through the narrow slits between the swollen lids. But instead of the pasty nephritic pallor, the patient's colour was almost black, a tint observed only in extreme cyanosis. The visible veins were distended and tortuous. The contrast between the bloated, dark upper half of the body and the pale, emaciated lower portion was remarkable. The patient had the spindle legs of the last stage of wasting disease without œdema. The abdominal wall was slightly œdematous above the umbilicus. The line of separation between the pale, flaccid abdominal wall and the swollen, purplish chest wall, which was hard and brawny, pitting only on firm pressure, was almost as clear cut as the line of demarcation in a case of gangrene. The cardiac outline was difficult to determine because of the thick, œdematous chest wall. At the base of the heart and over the manubrium was an increased area of dullness. A systolic murmur, which lasted into the diastole, was heard over the precordium and in the interscapular region. At the aortic cartilage it was most intense, continuous, soft, blowing, and somewhat humming. Numerous râles, moist and dry, were heard over the lungs, particularly behind. At the bases there was some dullness, with obscuring of breath sounds, as from pleural effusion. Breathing grew more and more difficult, dysphagia developed, and sleep was possible only by the aid of drugs. A radiogram showed a shadow as from an aneurysm of the aortic arch. He gradually lost strength, and died eight days after he came under observation. The necropsy showed old and active aortitis, typically syphilitic. The aneurysm originated 4 cm. above the aortic valves. The sac projected so as to press on the superior cava, especially near the heart. The opening into the vena cava was 1·5 cm. in diameter. The innominate and azygos veins were much distended.

---

[1] American Journal of the Medical Sciences, December, 1919.

The case narrated conforms to the description given by Pepper and Griffith[2] in their classical paper on Rupture of Aortic Aneurysm into the Superior Vena Cava. They found records of 29 cases. With the present case the number now reaches 43. While the typical case permits of diagnosis, variations in the size of the aneurysm, in the point of pressure, and in the degree of obstruction may cause difficulty. Treatment can be only palliative. Bleeding has been of only temporary benefit. Death may occur soon after the accident, or be postponed many weeks or even months.

SILENT RENAL CALCULI.

Dr. Edmund L. Young, jun.,[1] of Boston, states that in 3960 autopsies performed at the Massachusetts General Hospital since 1896 stones were found in the kidney or ureter or both in 45 cases. In 7 cases operations had been performed for stone, and one small stone out of many, or a fragment from a large stone, had been lost in a pyonephrotic cavity. In a bilateral case one side had been operated on and the other was to have been done later. One case with calculous pyonephrosis died without operation. In the remaining 37 cases the patients were in hospital for some other condition than stone in the kidney. Stones were known to be present in three of these, but had nothing to do with the condition from which the patient suffered and ultimately died. There was only one case with a completely negative history and urinary findings and a normal kidney on naked-eye and microscopic examination, but there were four cases without symptoms and with a negative urine, six cases without any damage to be demonstrated at the autopsy, and 15 cases in which the damage was too slight to compromise the integrity of the kidney. On comparing the clinical and pathological aspects it was found that one patient who was known to have had a stone for six years had a negative urine and a normal kidney. Another patient who had passed stones for at least seven years had a negative urine and a kidney which was normal apart from a very slight dilatation. Of the four cases without symptoms and with a negative urine only one showed an entirely normal kidney; it contained many small stones in the calices and the pelvis. The other three were, however, essentially normal, some interstitial changes and atrophy of renal elements being the only lesions noted.

MULTILOCULAR HYDATID DISEASE.

Multilocular (also called alveolar) hydatid disease was first recognised and described in Germany by Virchow in 1855. Previous to his description, the cases when met with appear to have been regarded as alveolar colloid cancer. The liver was for a long time the only organ known to be affected, and the few recorded cases have come principally from Russia, South Germany, and Switzerland. Writers have been much exercised as to the way the formation arises. It is known that exogenous budding, with the production of external daughter-cysts, is a phenomenon exhibited by some hydatid cysts, just as internal daughter-cysts occur from endogenous growth. It is stated by Neumann that the two kinds of budding—exogenous and endogenous—are not generally found in the same echinococcus, nor in the same host. If this is true, it would seem as if there existed either an influence derived from the tissues of the host or a special propensity implanted in some races of the parasite.

After the typical picture of multilocular hydatid had been established from examination of liver specimens a new series of echinococcus tumours began to be observed. These appeared to have their primary seat in bone. Virchow stated in 1883 that multilocular hydatid of the liver and hydatid of bone were the same disease. Moreover, he regarded the echinococcus of the multilocular form and that of the cystic type as the same parasite under different conditions of life, and especially of pressure in dense tissues. This theory would hardly suffice to explain why the cysts continued to be small in collections situated in the soft tissues of the interesting case described by Dr. C. E. Corlette, of Sydney, in our present issue; for instance, those in the left thigh, in the right retroperitoneal region, or above the spleen. Compression could not there be the cause of their small size, and it is probably partly a question of nutrition and partly of the mechanical conditions, since the cysts were naked and quite free, like marbles in a bag, and the large ones probably got ruptured.

Dr. J. B. Cleland, principal microbiologist of New South Wales, has compiled a bibliography and short abstract of those cases of hydatid disease of bone recorded in Australian periodical literature. About 18 separate cases have been recorded, of which 5 are in the femur, 3 in the sacrum or coccyx, 2 in the tibia and the ilium, and 1 in each of the following bones: vertebra, skull, superior maxilla, humerus, a rib, terminal phalanx of a finger. The records show that when the bones of the limbs have been attacked there has been a marked propensity to fracture, and that the nidus has practically always been in cancellous bone. The question how the hydatid embryo gains its entry to the bone, and the cause of its predilection for certain bones, remain obscure.

---

[2] Trans. Assoc. of American Physicians, 1890.

[1] Boston Medical and Surgical Journal, Nov. 13th, 1919.

The suggestion that multilocular hydatid disease is caused by a parasite distinct from *T. echinococcus* was made by Melnikow-Raswedenkow, and appears to have impressed the late Sir Edward Stirling and Sir Joseph Verco, who gave an extensive abstract of his views in Allbutt and Rolleston's "System of Medicine" (1905). The theory is founded on the structural difference between the cysts, and especially on the presence of reproductive material on the outside of, as well as within, the cysts in the alveolar as opposed to the hydatidiform cysts; also, on the far greater inflammatory reaction in the surrounding tissues in the alveolar form. However, since it is stated by Stirling and Verco that certain cases, at any rate, of hydatid infestation of bones contain the ordinary *Echinococcus hydatidosus*, the association in Dr. Corlette's case of bone hydatid and multilocular hydatid disease of the lung becomes interesting in connexion with the ætiology. The coincidence of a double infection in one individual seems on the whole more improbable than a different form of lesion caused by the same parasite under different conditions. On the other hand, the geographical distribution of multilocular hydatid disease in man is a point in favour of its separate origin. C. W. Stiles and Ramsay Smith take this view, though the latter, working in South Australia, has found over 1000 cases of multilocular disease in animals. The problem is not yet settled, but the curious lesions in Dr. Corlette's case suggest that after all one parasite may be the cause of all hydatid infections.

A LONG list was announced last week of appointments to the civil division of the Order of the British Empire for services during the war in connexion with military and civil hospitals, command depôts, and convalescent camps. Mr. J. F. Colyer, whose work at the Croydon War Hospital has marked an epoch in the treatment of injuries of the jaw, becomes a Knight of the Order, and about 140 names appear as Commanders, Officers, and Members. We call special attention to the list of Commanders given on p. 349, since the *Times* of Jan. 31st conferred a week-end knighthood on these gentlemen, whose embarrassment was not entirely outweighed by the pleasure given to their friends.

AS we announced last week, Dr. R. J. Reece, C.B., has been appointed to be one of the senior medical officers of the Ministry of Health, and the appointment has caused much satisfaction in the service. Dr. Reece's comprehensive knowledge of preventive medicine and his judgment and ability in dealing with matters relating to public health have long been recognised by those with whom his official duties have brought him in contact.

THE LANCET, Jan. 3rd and 10th, 1920.

THE Manager will be obliged to readers who have not any further use for their copies of THE LANCET of the above dates if they will kindly return them to him at 1, Bedford-street, Strand, W.C. 2. The postage on the numbers is one penny each. He will be pleased to pay for copies returned, as he is disposing of them again to new subscribers.

THE FEES OF OUR ANCESTORS.[1]

BY SIR D'ARCY POWER, K.B.E., F.R.C.S. ENG.

OF the fees gained by the medical profession we may say with Koheleth, the gentle cynic, "That which hath been is that which shall be; and that which hath been done is that which shall be done and there is no new thing under the sun." In the fourteenth century, which is the earliest period of which I have any knowledge of surgical fees in England, the conditions were very similar to our own. Fees were high and, at any rate on the surgical side, the patient was expected a threefold debt to pay. He paid a sum of money down, he contracted to give his surgeon an annuity of so much—seemingly as long as he survived—and he gave one or more suits of clothes—liveries—yearly. This was truly a full dress fee. Here are the details of such a transaction by John Arderne, an English surgeon living between 1307 and 1390, who says, "Ask of a great man an hundred marks or forty pounds with robes and a fee of an hundred shillings yearly for life. Of less men let him ask forty pounds or forty marks without further fees; and let him take not less than an hundred shillings for never in all my life took I less than an hundred shillings." The annual income of a labourer at this time may be estimated at £4, and out of this it was possible for him to save a pound. The surgical fees, therefore, were very high, and as many of Arderne's patients are known to have lived for many years after he operated upon them he ought to have amassed a considerable fortune. I am quite unable to discover how the surgeons at this time invested their money if they did not buy land, and many of them certainly did not do so. It was hazardous to lend to the Crown; there were no funds or Government securities, and there were no Jews. Although the fees were large the surgeon could not have had more than two or three patients a year, for it was his duty to live in the castle or house until the cure was complete, although there were certain itinerant surgeons, sons of Belial, who would take the fee in advance, operate, and then disappear on the following day. It was thought that such men brought discredit on the art of surgery.

Medical Fees in the Elizabethan Period.

The Wars of the Roses impoverished England in the fifteenth century, and very little is known of surgical practice until the time of Elizabeth, when payment for services rendered had undergone a great change. It was then usual to contract to cure the patient for a given amount, paid either wholly in money or partly in money and partly in kind, or perhaps very often wholly in kind, for surgeons at any rate were not particular as to how they were paid so long as they got something. Here again are instances of each method: "On 19th April, 1569, the wife of William Selby, of London, ironmonger, complained that William Wise had not cured her husband's leg as he promised to do, and it was ordered that he should repay again of the money which he received in part of the bargain six shillings and eightpence." A few years afterwards, on Oct. 2nd, 1576, "a complaint was made by Thomas Adams against John Paradice, because the said John had received money in hand and a gown in pawn for the remainder to cure the daughter of the said Thomas, which daughter died and the poor man made request for the gown again." The custom of contracting for a cure extended throughout the surgical profession at this time, for even William Clowes, the Queen's surgeon "was complained of by William Goodnep, in February, 1575, for not curing his wife *de morbo gallico*, and it was awarded that the said Clowes should either give the said Goodnep twenty shillings or else cure the wife." Clowes very wisely agreed to pay the twenty shillings. The fee at this time was a noble, and later an angel, for those who corresponded to our consulting physicians and surgeons. The practice of an annuity still lingered, for as late as 1660 Wiseman writes of a patient upon whom he had operated: "This person retired into the country and returned to London at the end of two years and acknowledged to me his cure by settling thirty pounds a year upon me during his life and paid me sixty pounds for the two years passed."

---

[1] A short address delivered at the Social Evening of the Royal Society of Medicine on Jan. 30th, 1920.

Origin of the Guinea Fee.

A new coin—the guinea—was struck in 1660, and it was quickly utilised by the doctors, who demanded it for a fee somewhat to the displeasure of the older generation, for the author of the "Levamen Infirmi" writes as late as 1700: "To the graduate in physic his due is about ten shillings, though he commonly demands or expects twenty; those that are only licenced physicians their due is no more than six shillings and eightpence, though they commonly demand ten shillings. A surgeon's fee is twelvepence a mile for his journey far or near; ten groats (3*s.* 4*d.*) to set a bone broke or out of joint; and for letting of blood one shilling; the cutting off or amputation of any limb is five pounds, but there is no settled price for the cure." The value of the noble, the angel, and the guinea, the successive units of fee in England, was never stable; the noble and angel varied from 6*s.* 8*d.* to 10*s.*, whilst the guinea, which was at first worth twenty shillings, sometimes rose as high as 30*s.*, and for many years was never less than 21*s.* 6*d.* A guinea was the regular consultation fee from the time of its introduction until about 1870, when the cost rose to two guineas. The two guinea fee remained until 1918, when it became three guineas.

Fortunes Made by Medical Men.

Very large sums of money were earned by successful physicians and surgeons in London during the eighteenth and nineteenth centuries, as there were few consultants in the provinces, and wealthy patients and serious cases gravitated to London. Dr. Radcliffe and Dr. Mead made their fortunes by seeing patients at their own houses or in consultation at a guinea apiece, whilst they wrote prescriptions for patients whom they had never seen (from descriptions of the case given by the apothecary in attendance) at half a guinea a bill. Dr. Radcliffe, when he was living in Bloomsbury-square, charged five guineas for a consultation at Bow. No inconsiderable portion of a successful consultant's income came from long journeys, and it is marvellous how they not only became inured to the fatigue and discomfort of travelling on bad roads, but were actually able to produce good literary work in their carriages. There is the well-known story of the collective power of the guinea in the case of the physician who declined to accept a fee from his patient, but was unable to refuse when the patient gave him a bag full of guineas filled by the simple process of dropping a coin into it after each visit; or the other story of the doctor who had his fee hurled at him by an eccentric patient and merely remarked that he would pocket the insult. There are several large fees on record. One of the best known is that received by Dr. Dimsdale, who left England at the desire of the Empress Catherine of Russia on July 28th, 1768, and returned in 1769. He introduced the inoculation of small-pox into Russia, and inoculated the Empress and about 140 other persons. He was rewarded for his services with the dignity of a Baron of the Empire, a present of £10,000, and an annuity of £500. The Dowager Lady Dimsdale has kindly referred to Baron Dimsdale's diary, and tells me that although the annuity is mentioned nothing is said about the present of money.

Another celebrated fee was received by one who, I am glad to say, is not a predecessor, for he is in robust health, and will, I hope, long remain so. It was a lakh of rupees, which at the present rate of exchange is worth £12,000, and by his kindness I am able to show you the illuminated tablet in Persian which accompanied the gift. Sir Peter Freyer received the fee in August, 1888.

Country Practitioners' Fees.

Very little seems to be known about the fees charged by country practitioners. Dr. Edward J. Cross, of St. Neot's, has kindly lent me a very interesting ledger showing detailed accounts of the firm, which still exists, for the years 1742–1755. Each item is priced, and ranges from 2*s.* for a bottle of medicine to 3*d.* and 6*d.* for a pill, whilst a visit, or "iter" as it was called technically, was from 2*s.* 6*d.* to 4*s.* 6*d.*, according to the distance. The total account rarely exceeded £5, and was usually under £1. The patients paid at long intervals, and generally only part at a time. We know from the evidence given by Abernethy at the Royal Commission in 1834 that these charges were the usual ones in the country, for he states that "I was called into the country to see a patient in consultation with his family practitioner and I ordered the patient a pill. When we left the room the doctor said, 'Do you mind making that pill into a mixture?' I said, 'What difference does it make?' He replied, 'None to you but much to me. If you order him a pill I shall have to come to-morrow to see how it has acted and I shall only get threepence for my trouble and I must supply the pill, but if you put it into a bottle I shall receive a more adequate fee.'" Indeed, until 1815 the general practitioner was remunerated entirely by the amount of medicine he could induce his patients to swallow and not at all for his skill and attention. The end of this bad practice was a side issue of the tax upon glass imposed in 1812. Bottles became so expensive that the general practitioner was obliged to reconsider his position, and thence arose the agitation which culminated in the Medical Act of 1815. The practice of extensive dosing lingered amongst the people until our own time, and the familiar expression of "a blue pill and black draught" is a reminiscence of the time when 6 or 12 1-oz. phials were sent out in packets neatly wrapped up in white paper, each phial having a single blue pill in a small box, with white ends and a red body, perched upon the top of the cork. The price was 1*s.* 9*d.* a draught and pill, and there was, I presume, a handsome profit, which was lost when 8-oz. and 12-oz. mixtures came into vogue.

Conclusion.

And thus I come back to Koheleth's statement that there is nothing new under the sun, for if we consider the relative purchasing power of money in the eighteenth and twentieth centuries our predecessors were better paid than are the majority of the medical practitioners at the present time. The type of practice has changed; the type of mind remains. The older generations demanded bleeding and plenty of physic; the modern generation asks for serums, vaccines, and intravenous injections.

THE SCOTTISH BOARD OF HEALTH:

CONSULTATIVE COUNCILS.

IN the Act which established the Scottish Board of Health provision was made for the setting up of Consultative Councils to advise and assist the Board in connexion with Scottish health matters. The constitution and functions of these Councils were defined by an Order in Council of Dec. 20th last. The Councils, which are four in number, deal with the following matters: (1) Medical and allied services; (2) National Health Insurance (Approved Societies' work); (3) local health administration and general health questions; (4) Highlands and Islands.

The appointment of the members of the Councils rests with the Board, who have now completed their selection of the personnel of each of the four Councils. The membership of the several Councils as announced by the Board is as follows:—

1. MEDICAL AND ALLIED SERVICES.

Orlando Charnock Bradley, Esq., M.D., D.Sc., M.R.C.V.S., Principal of the Royal (Dick) Veterinary College, Edinburgh; Vice-President of the Royal College of Veterinary Surgeons; President of the National Veterinary Medical Association.

A. J. Campbell, Esq., M.D., Secretary of the Berwickshire Local Medical and Panel Committees.

A. K. Chalmers, Esq., M.D., Medical Officer of Health for the City of Glasgow.

D. Elliot Dickson, Esq., M.D., Convener of the Fife Colliery Surgeons' Committee.

J. R. Drever, Esq., M.B., Scottish Medical Secretary of the British Medical Association.

Miss Annie W. Gill, Lady Superintendent of Nurses, Edinburgh Royal Infirmary.

John Glaister, Esq., M.D., Professor of Forensic Medicine and Public Health in the University of Glasgow.

Professor Matthew Hay, M.D., Medical Officer of Health for the City of Aberdeen.

John Rutherford Hill, Esq., Resident Secretary of the Pharmaceutical Society in Scotland; Secretary of the General Council of Panel Chemists (Scotland).

Sir Donald MacAlister, K.C.B., M.D., Principal of the University of Glasgow; President of the General Medical Council.

John Yule Mackay, Esq., M.D., LL.D., Principal of the University College, Dundee.

Sir James Mackenzie, M.D., F.R.C.P., Clinical Institute, St. Andrews; Consulting Physician to the London Hospital.

Sir Robert William Philip, M.D., F.R.C.P., Professor of Tuberculosis and Senior Lecturer on Clinical Medicine in the University of Edinburgh; President of the Royal College of Physicians, Edinburgh.

James Maxwell Ross, Esq., M.B., C.M., M.B.E., Medical Officer of Health and Chief School Medical Officer for the County of Dumfries.

Miss Laura Stewart-Sandeman, M.D., late Controller of Medical Services to Queen Mary's Army Auxiliary Corps, Overseas.

Sir Harold J. Stiles, K.B.E., Regius Professor of Clinical Surgery in the University of Edinburgh.

F. Tocher, Esq., D.Sc., Public Analyst for the County of Aberdeen, &c.; Honorary Secretary of the Association of Public Analysts of Scotland.

Norman Walker, Esq., M.D., General Medical Council.

George Williamson, Esq., M.D., Chairman of Aberdeen Local Medical Committee.

John A. Young, Esq., L.D.S., J.P., Vice-President of the Odonto-Chirurgical Society of Scotland; Convener of the Public Health Committee, Edinburgh Town Council.

2. National Health Insurance (Approved Societies' Work).

Thomas J. Addly, Esq., Secretary of the Scottish Professional Assistants' Society and of the St. Andrews and Edinburgh Diocesan Insurance Society; President of the Edinburgh, Leith, and District Friendly Societies' Council.

Neil Beaton, Esq., National Amalgamated Union of Shop Assistants, Warehousemen, and Clerks; ex-President of the Scottish Trade Union Congress.

Hugh Berrie, Esq., Secretary of the British Order of Ancient Free Gardeners.

David Bertram, Esq., J.P., High Chief Ranger, Ancient Order of Foresters' Friendly Society.

Miss May Dunbar, Secretary of the Scottish Women's Friendly Society.

James Gold, Esq., Secretary of the Scottish Miners' Federation Friendly Society.

John C. Hendry, Esq., J.P., Secretary of the Brechin Mill and Factory Operatives' Union; President of the Scottish Textile Workers' Federation.

Thomas McMeekin, Esq., Glasgow District Secretary of the Independent Order of Rechabites; President of the Scottish Conference of Friendly and Approved Societies.

Miss Annie McRobbie, Secretary of the North of Scotland Women's Insurance Society.

W. S. Rimmer, Esq., J.P., Inspector (Glasgow District) Prudential Assurance Company, Limited.

W. M. Shaw, Esq., Manager of the Scottish Legal Health Assurance Approved Society.

Miss Eleanor Stewart, Workers' Union.

William Thomson, Esq., Secretary of the Scottish Coöperative Friendly Society.

Peter Webster, Esq., Secretary of the Scottish Horse and Motormen's Association.

William Wood, Esq., Secretary of the Scottish Rural Workers' Friendly Society.

3. LOCAL HEALTH ADMINISTRATION AND GENERAL HEALTH QUESTIONS.

The Most Honourable the Marchioness of Aberdeen and Temair, President of the International Council of Women,

Robert Allan, Esq., Secretary of the Scottish Trade Union Congress.

Sir Henry Ballantyne, D.L., Chairman of the Royal Commission on Housing (Scotland).

Joseph F. Duncan, Esq., Secretary of the Scottish Farm Servants' Union.

J. B. Fergusson, Esq., Ayr County Council.

Andrew Grierson, Esq., Town Clerk of Edinburgh.

Joseph Johnstone, Esq., M.P., Renfrew County Council; President of the Scottish Association of Insurance Committees.

William Jones, Esq., Clerk to Glasgow Insurance Committee.

H. S. Keith, Esq., ex-Provost of Hamilton.

W. W. Kelson, Esq., Chief Sanitary Inspector, Paisley.

Mrs. Mary Burns Laird, Scottish Labour Housing Association.

Lady Leslie Mackenzie, Vice-Chairman of Edinburgh Insurance Committee; President of the Scottish National Association of Health Visitors and Women Sanitary Inspectors.

W. M. Marshall, Esq., Clerk to Lanarkshire Insurance Committee; Secretary of the Scottish Association of Insurance Committees.

Sir Thomas Munro, K.B.E., County Clerk of Lanarkshire.

Thomas G. Nasmyth, Esq., M.D., D.Sc., ex-President of the Scottish Society of Medical Officers of Health; formerly Medical Superintendent of Perth Infirmary.

Malcolm W. Scott, Secretary of the Society of Inspectors of Poor and Poor Law Officers of Scotland.

James Stewart, Esq., Glasgow Town Council (Convener of Health Committee).

Joseph Sullivan, Esq., M.B.E., Lanark County Council; Secretary of the Scottish Labour Housing Association.

James Thomson, Esq., City Engineer, Dundee; Vice-President of the Institute of Municipal and County Engineers.

W. E. Whyte, Esq., O.B.E., District Clerk, Middle Ward of Lanarkshire.

4. HIGHLANDS AND ISLANDS.

Her Grace the Duchess of Atholl, D.B.E., Member of the Highlands and Islands Medical Service Committee; President of the Perthshire Federation of District Nursing Associations.

John Birnie, Esq., J.P., ex-Provost of Inverness; Chairman of Inverness Burgh Insurance and Local War Pensions Committees.

William Durran, Esq., J.P., ex-Provost of Thurso; Chairman of the Insurance Committee for the County of Caithness and of the County Education Authority.

Rev. Wm. Fotheringham, J.P., Vice-Chairman of Zetland County Insurance and Local War Pensions Committees; Late Vice-Convener of the County and Chairman of the Mainland District Committee.

Lady Susan Gilmour, late Member of the Highlands and Islands (Medical Service) Board.

Miss Bella Jobson, Secretary of the Scottish Fish Workers' Friendly Society.

Mrs. Helen Kerr, Member of the Royal Commission on Housing (Scotland).

The Maclachlan of Maclachlan, Convener of the County of Argyll.

Miss Sybil M. Macphail, Honorary Secretary of the Ladies' Highland Association.

Dr. A. C. Miller, J.P., Chairman of the Highlands and Islands Subcommittee of the British Medical Association (Scottish Committee).

Wm. J. Munro, Esq., J.P., Clerk to Easter Ross District Committee.

Dr. Donald Murray, M.P., Late Medical Officer of Health for Lewis.

Dr. James B. Simpson, J.P., D.L., Vice-President of the Sutherland Nursing Association and Secretary to the County Local Medical Committee.

Miss Margaret M. White, Superintendent of Queen Victoria's Jubilee Institute for Nurses (Scottish Branch).

Each Consultative Council will, in terms of the Order in Council, appoint its own chairman. Mr. George A. Birse, Scottish Board of Health, 125, George-street, Edinburgh, will act as secretary to the Councils.

MEDICAL CARE IN INDUSTRY.

THE appeal of modern preventive medicine, directed, as it is, at the individual, instead of being confined as heretofore chiefly to the sanitary conditions of life, may be said to be concerned with three stages; (1) Obtaining a healthy population by supervision of births and infant life, what is known as maternal and infant welfare; (2) supervising the growing child, carried out through school medical service; and (3) maintaining in health the adult worker.

This country is probably abreast, if not ahead, of other civilised countries with regard to the first two stages, but we are behind America with regard to the last. Something we are doing through the activities known as "industrial welfare," which received, through the influence of the Ministry of Munitions, a great impetus during the war in the engineering trades; and we have to-day a powerful Welfare Supervisors' Association over 1000 strong, an Industrial Welfare Society (representative of an important group of employers), the powers of the Home Office in relation to welfare accommodation, and the work carried on by the training section of the Ministry of Labour. But the work, as readers of semi-popular journals and the daily press can testify, is steadily drifting into lay hands; the medical profession is only called in here and there to help; it is not as it ought to be the fons et origo of this important branch of preventive medicine. Presently the profession will discover that vested interests have been created which stand in the way of its true recognition and influence.

Industrial Medicine in the United States.

Advance in the United States is proceeding on different lines, and these are clearly indicated by the Public Health Bulletin, written by C. D. Selby, on the Medical and Surgical Care of Industrial Workers.[1] Industrial medicine is therein recognised as a new and interesting science, a branch of the science of industrial management on the one hand, as it is of preventive medicine on the other; "a compromise between the ideals of medicine and the necessities of business." Mr. Selby defines industrial medicine as "the theory and practice of medicine applied to the purpose of preventing and alleviating sickness and injury among industrial workers in order that they may enjoy the benefits of continuous productive employment"; and he points out its value both to employers and to workers.

---

[1] Studies of the Medical and Surgical Care of Industrial Workers. By C. D. Selby. Public Health Bulletin, No. 99. 1919. United States Public Health Service, Washington.

Adoption of work on the lines of this definition gives to industrial medicine a clear line of action and a duty to fulfil, so that workers shall no longer feel themselves slaves,

> Hardened to hope, insensible to fear,
> Scarce living pulleys of a dead machine,
> Mere wheels of work and articles of trade,
> That grace the proud and noisy pomp of wealth!

The report is based upon information obtained from 155 industrial establishments as to the medical activities carried on. These establishments employed 20 consulting physicians, 68 whole-time physicians, 50 part-time, and 37 on call—i.e., 175 physicians in all—and in addition 13 dentists, while there were dispensaries at 137. These figures show how this new science in the States is under the direction of the medical profession. The factory doctor can make his value felt in every stage of industrial life:—

(i.) At industrial birth—in selecting workers suited to their work. The effect produced can only be appreciated by contrasting it with the present way of engaging workers by the method of trial and error with its attendant financial waste and instability for labour: under this method it is usual to-day to engage annually 1000 new workers to maintain a personnel of 1000, and Mr. Selby quotes one company in which the labour turnover for the year 1917 was somewhat over 400 per cent. Every engagement represents a cost of about £1. Careful selection lessens the turnover by not less than two-thirds, and the money saved is sufficient of itself to carry the cost of industrial medical service.

(ii.) Throughout industrial life—in supervising the health of the workers and the hygiene of workplaces. Medical attention to personal ailments, small at their start, lessens lost time and promotes working efficiency; this is given at the ambulance room or dispensary. Tours of inspection are required to ensure adequate sewage and waste disposal, washing and toilet facilities, ventilation, illumination, heating or cooling apparatus, blowers, exhaust draughts, floor and window cleaning, and pure drinking water. Machinery, tools, and methods of work call for medical attention to reduce to a minimum hazards to health and body. Health instruction and dental prophylaxis are essential parts of the work. Supervision of the provision, during attendance at the factory, of food suitable in quantity and quality to the work is a physiological question. Hours of labour in relation to fatigue, with facilities for rest and recuperation, can only be scientifically arranged by a medical expert in industrial hygiene. Accident prevention, effected by the safety-first movement, is essentially psychological in aspect. These are some of the medical aspects of industrial life.

(iii.) At threatened industrial demise—in restoring to productive activity those who have temporarily broken down or sustained some incapacitating injury. Organisation of first-aid treatment and ambulance squads are called for here. Out-patient work, medical and surgical, at the ambulance station makes a constant demand for service. Visitation of sick or injured workers in their homes is often needed. After-care and training of those in any way maimed can, in medical hands, often restore to usefulness those who must otherwise drift among the unemployable: a discovery which the Pensions Ministry in this country is now demonstrating for the enlightenment of industry. Mr. Selby tells of two blind men found in the plant of a large electric motor company, and of 51 crippled employees at the factory of an Ohio shoe company!

Where and How Medical Service should Start.

The report considers that: "An establishment employing anywhere from 200 to 500 people is warranted in having a dispensary; that such an establishment is justified in having either a whole-time or part-time physician; and that if he be on a part-time basis his services may advantageously be augmented by a trained female nurse or a person who has been taught to handle the routine work under his direction."

The need in larger establishments is, of course, still greater; and where from 500 to 1000 persons are employed the part-time services of a dentist for prophylactic service is considered warranted. The personnel and organisation of medical departments in establishments employing different numbers of employees is usefully discussed and set out. But attention is drawn to the need for physicians trained in industrial medicine: those who drift into the work tend to drift with it; and those who act as "finger wrappers" for the money it gives them are a reproach to the science. What is wanted is men "giving their brains and hearts to industry, striving at all times to better conditions among the working people, and to benefit industry itself." The advice given to the industrial doctor for arranging his work is, "organise, deputise, and supervise"; and training and aptitude are required for its adoption. The place of the dispensary attendant and factory nurse is set forth clearly, and the need for adequate clerical staff.

Good plans and illustrations of dispensaries and medical quarters are given in the report, which is worth consulting on this account alone; and attention is also directed to equipment, furniture, and fixtures. The practical information given in these portions of the report will be of the greatest use to those called upon to advise manufacturers wishful to embark upon this remunerative branch of industrial management.

Industrial Medical Activities.

The following summary is worth quoting verbatim to indicate the wide field of work which comes within the boundaries of industrial medicine:—

1. Treatment of injuries in dispensary, home, or hospital, by physician, attendant, or consultant, including orthopædic and reconstructive surgery when necessary.
2. Opinions as to disabilities from injury and recommendations as to compensation awards.
3. Rehabilitation of impaired workers.
4. Consultation and service, including dental, for the alleviation of ailments that become evident during hours of employment.
5. Assistance in obtaining skilled medical, dental, and nursing attentions when employees themselves are unable to procure them.
6. Visits on sick absentees to assist in treatments, to render social aid, or to instruct.
7. Regular factory inspection designed to uncover conditions that are inimical to health, and written recommendations to proper officials for their correction.
8. Studies of the effects of methods, processes, and machinery operations upon health and body functions, relating to posture, eyestrain, monotomy, speed, poisons, &c. Written recommendations to proper officials when effects are found to be harmful, and advice to employees which will enable them to minimise the harmful results of processes from which hazards cannot wholly be removed.
9. Physical examinations of applicants for employment, and written recommendations to employing officers relative to applicants' fitness for work.
10. Examinations of applicants for re-employment when the periods of absence warrant them.
11. Examinations of employees when their shop efficiency falls off, unless the reasons are evidently not physical; advice and treatment, or aid in obtaining treatment, to such as need it; and written recommendations to foremen when deemed wise.
12. Examinations of employees returning to work after sickness or injury and written recommendations to employing officers and foremen if employees are not fully restored.
13. Examinations of employees who do not feel well or do not appear well to their foremen or fellows; advice to employees when it is indicated; and written recommendations to foremen if altered working conditions are essential.
14. Examinations of workmen ceasing employment after having been exposed to special health hazards and explicit records of their conditions.
15. Frequent examinations to follow up previous findings.
16. Monthly examinations of all process workers, those who may be engaged in any work that may in any way have ill effects, and of food handlers.
17. Epidemiological service including intimate coöperation with municipal health authorities.
18. Health instruction by personal talks in the homes or factory, by lectures, posters, or pamphlets.
19. Records of data that will assist in the prevention of accidents and sickness.
20. Records of facts that will enable employers and employees to obtain equitable compensation adjustments.

21. Records of information that will show the scope and ,lue of all medical activities.
22. Studies of facts and data with the view to developing ientific knowledge and usefulness.
23. Contributions to scientific and trade publications.
24. Attendance at meetings of scientific societies.
25. Constant efforts to merit and retain the confidence the employees and the approbation of the employers.
26. Frequent conferences with those in authority.
27. Coöperation with other establishments and local, ate, and National Health authorities.
28. And finally, the admonition to organise, deputise, id supervise, remembering always that anything which important enough to do is sufficiently important to be one well.

Records and Reports.

Work of the kind here indicated cannot be done ithout organisation, and organisation is not possible ithout records and reports. Mr. Selby has taken uch trouble in setting out and discussing the value of ie records found in use, and the way in which they hould be employed to ensure efficiency and rapid work. he diversity of forms adopted makes him appeal for ome standardisation: and we cordially agree that much dvantage would accrue therefrom. In this country we nderstand that an effort in this direction is likely to be iade; and that a set of forms recommended for use iay soon be placed before manufacturers by a Government department.

No useful purpose would be served by discussing the orms reproduced in the report at length; we need only oint out that while summary reports are needed by ndustrial officials, which should be as simple and oncise as possible, they must be based on detailed ecords which incidentally are invaluable for the ursuit of scientific knowledge. Every industrial hysician should be a research worker in this new field, nd make full use of the experiments continually, even hough unintentionally, being carried out in the establishment he is attached to. The need for knowledge in ndustrial medicine is to-day great and pressing when he whole world is calling for production, production, nd again production; it is required to enable the ndustrial worker to multiply his output without detriment to his health and contentment—that detriment which is the foundation of industrial unrest and strikes, vith their inevitable drag on the wheels of social rogress.

Industrial medicine can here play an important part, ecause, as Mr. Selby justly writes, it "is not only iumane but essential to production. It is beneficial to workers and profitable to employers. It offers splendid idvantages to physicians for the development of careers n a field of rapidly growing importance, vital with pportunities for service to humanity."

ALLEGATIONS OF PROFITEERING:

A COMPLAINT FROM THE MEDICAL RESEARCH COMMITTEE.

AT a meeting of the Complaints Tribunal of the Central Committee, held on Jan. 30th at the Hotel Windsor, Victoria-street, S.W., a complaint was investigated which had been lodged by the Medical Research Committee, of 15, Buckingham-street, Strand, W.C., regarding the price of a gallon of collodion solution which was supplied to them by the British Zylonite Co., Ltd, of Hale End, London, E. The complainants alleged that they were charged £14 10*s.* 7*d.* for a gallon of the solution which they had previously purchased from the respondent company at a cost of 17*s.* 6*d.*

Dr. H. W. Dudley, who appeared in support of the complaint, mentioned that the Medical Research Committee conducted general medical research for the purpose of combating disease. He recalled the fact that in 1915 a paper was written in which the author mentioned that the British Xylonite Co. were willing to supply the solution, which was essential for some research work. That was not a customary step to take when research work was published, and the result would be that other people would apply for the solution when it was recommended by a known research worker. In September, 1915, a purchase of two gallons of the solution was made from the respondents at a cost of 17*s.* 6*d.* a gallon. Last September a gallon of the solution was ordered, and when the invoice arrived the Committee was intensely surprised to find that a charge was made of £14 10*s.* 7*d.* It refused to accept the solution, which was returned to the company, who sent them a credit note for the amount charged. The Committee extracted a small portion of the solution from the bulk, which it offered to pay for, but no charge was ever made for it. The witness gave it as his opinion that there was no reasonable explanation for a rise in price of over 1500 per cent. The Committee brought the complaint as it had in the first instance recommended the solution publicly, and it also felt that it should take strong exception to excessive charges made for materials which were used in research work.

In answer to the Chairman of the tribunal (Sir Herbert Neild, K.C., M.P.) it was stated by Dr. Dudley that the Committee was now purchasing a solution elsewhere which answered its purpose at a price of about 28*s.* a gallon.

Replying to Mr. A. Brammall, solicitor, who appeared for the company, the witness agreed that the price of the ingredients used in the solution, such as ether, methylated spirit, and nitro-cellulose, had considerably advanced in price during the last few years, while labour had also gone up considerably.

Dr. Dudley further stated that the formula for the solution was supplied to the manufacturers by the Medical Research Committee. He was not aware that before the war the solution could only be obtained from Germany, and pointed out that there was nothing very difficult about the making of the stuff. He did not know that in 1915 the respondent company was specially asked to make the solution as it could not be obtained elsewhere.

Mr. Brammall said that the charge of £14 was a mistake and was never intended. If, when the Committee complained, it had mentioned that it had been charged £14 the whole matter would have been rectified at once, and a full explanation given. The correct charge was 37*s.* 6*d.* The solution was sold as a solid or in liquid form. As a solid the price was 37*s.* 6*d.* per pound, while the same amount was charged for a gallon. The explanation was that when a gallon of the solution was evaporated there remained 1 lb. of solid matter which were called "chips." When the employee of the company to whom the order was handed saw that a gallon was ordered he thought that a gallon of the solid substance was required. He estimated a gallon as being equal to 3½ kilos or 7 lb. 12 oz., and the charge of £14 odd was made out in that way. His clients were specially requested to make the solution in 1915 when the supplies from Germany were exhausted. The company did not want to make it, and they only consented from patriotic motives, as they were told that medical people required it for the relief of suffering manhood. Literally and truly they only commenced the manufacture from philanthropic and patriotic motives. Between 1916 and 1919 the turnover of the company was four millions sterling, while in the four years the sales of the solution only amounted to £80. From a business point of view the company ought never to have touched it, and would rather not have had the business. The company had a very high reputation in the country. He also pointed out that between 1915 and 1918 no orders for the solution were received, and only "chips" were sold by the company.

Mr. T. R. Brooke, the commercial manager of the company, said that in 1915 he was told by the Medical Research Committee that Schering's collodion was no longer procurable, and, as it was required, they undertook to produce collodion, being told how it was produced. The price had increased from 17*s.* 6*d.* a pound or gallon to 37*s.* 6*d.*

The Chairman: That increase would not be complained about.

Mr. Brooke further stated that when the complaints were received there was nothing in the letters to show that £14 had been charged. It was not until they received a communication from the tribunal that they realised a mistake had been made.

Sir William Pearce, M.P., the treasurer of the Manufacturing Chemists' Association, gave evidence of the high reputation which the respondent company enjoyed.

Mr. Brammall: Do you think the company would intentionally make a charge of this sort?—My experience of the company has been a very long one, and I am certain that no one in a responsible position would do anything of the sort.

What reputation do they bear in the commercial world?—The highest possible character. They are a firm whose word may be taken. Their word is their bond.

Mr. Claud Walterer, a clerk in the employ of the company, stated that he was responsible for the mistake. He found on referring to another order that 37*s.* 6*d.* a lb. was charged, and reckoned a gallon of the "chips" as being 3½ kilos.

In answer to further questions the witness said that one other mistake had been made in dealing with the solution. Messrs. Burroughs, Wellcome and Co. ordered a quart and were charged £3 12*s.* 7*d.* No complaint was made by the buyers, but when the present case came to light an investigation of the company's books took place. The mistake made in regard to Messrs. Burroughs, Wellcome and Co. was discovered, and a refund was made. He was the clerk responsible for the error.

The Chairman, in giving the decision of the tribunal, said they were of opinion that this case was an exceedingly grave one. The explanation forwarded by the respondents on Jan. 2nd was not what one would call a complete and full statement of the facts in relation to the sale of the article. What the tribunal thought was responsible was a system which had grown up in modern times of calling upon departments to justify their existence; and the tribunal rather thought that the department, in relation to these two applications for the liquid article, might have been careless, more than careless, in regard to the method of booking them up, in order to justify themselves in relation to the general trade of the concern. The tribunal were, of course, confronted with the fact that this was a limited company, and one which was doing a very extensive business, and if the case were sent for prosecution it would rest upon the individuals constituting the company to justify themselves in order to take advantage of the section of the Act relating to limited companies. The tribunal thought that, upon the whole, it would suffice if they marked their displeasure at the way in which this transaction had been carried on by saying that, putting the most moderate construction upon it, it had been grossly careless, and such as to produce the impression in the minds of those accustomed to business, and to the precautions ordinarily taken, that it was a gross and bad case. For all that, they thought that the blame was not so much upon those who would reap the benefit of the overcharge as upon the careless way in which those in charge of the department had behaved. It was almost incredible that, two letters having been received from a public department whose custom one would have thought the respondents would have tried to retain, there was, in the interval between the making out of the invoice and the credit note, apparently no attempt to inquire more particularly into the matter, the goods being simply accepted when returned and the credit note sent, leaving the department to get the material when and from where they could. The tribunal entertained very grave doubts as to whether they were doing quite the right thing, but on the whole they thought that a censure was sufficient, and that the complaint, subject to that censure, must be dismissed.

Hospital Sunday in Bristol was observed on Jan. 25th. A strong appeal was made by the Lord Mayor, who stated that in one year 101,080 patients were treated at an expenditure of £71,000, which sum was nearly £18,000 more than the year's income. Last year the record amount of £5000 was raised, and this year it is confidently hoped that the collections will be still larger.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Irish Public Health Council.

THE Irish Public Health Council did much importar business at its last session held on Jan. 20th to 22n On the first day the Council received a deputatio representing the National Association of Approve Societies. The deputation spoke chiefly of the necessit for providing an efficient medical service for insure persons and their dependents, and pointed out tha if a system of medical benefits or treatment fo insured persons were established in Ireland conside able funds from insurance sources would be availab towards financing such a medical service; but was essential that it should not be in any wa associated with the Poor-law Medical Service. member of the deputation, who represented th Prudential and the National Amalgamated Approve Societies, stated that the incidence of sickness amon their members was twice as great in Ireland as i England, and he attributed this to the absence i Ireland of a proper system of medical treatment. I the course of a discussion which followed, the deputatio stated that the Approved Societies would conside favourably the question of allocating towards ho pital and allied services, and for the treatment o dependents, part of any surplus funds which migh be available after the forthcoming valuation. Th deputation also agreed that there would be no obje tion to a medical service system under which insure persons would pay the medical practitioners an who would also be responsible for the treatment o persons unable to pay. Subsequently the Counc arrived at important decisions concerning the followin matters: The constitution and function of the propose central health authority in Ireland and of count health authorities; the establishment of an Iris Medical Service, which would provide medical trea ment for insured persons (and, if possible, for thei dependents) as well as for persons unable to pay; an the reorganisation and coördination of the hospita system in Ireland, with a view to providing treatmen for the classes able to pay, not only in the count institutions, but also in the voluntary hospitals in th larger cities. These questions and previous decisions o the Council were referred to a Drafting Committee, cor sisting of the chairman, Dr. E. Coey Bigger, Sir Josep A. Glynn, and Dr. R. J. Rowlette, to be embodied in th report to be made by the Council to the Chief Secretary

Belfast and the Irish Public Health Council.

A meeting of Belfast doctors—summoned by th chairman and secretary of the Local Medical Com mittee, through a notice in the public press, "to review the present position of the medical profession in rela tion to the new Public Health Council and to con sider the possibilities of State Medical Service an kindred schemes"—was held in the Medical Institut on Jan. 30th, when there was a large attendance. Th chairman of the Local (Belfast) Medical Committee Mr. R. J. Johnstone, who presided, gave an account o the present position. He explained that the Irish Publi Health Council, who was at present engaged in draftin its report, would probably make £3 a week the limit o income of those to be attended gratuitously, that ther would be a National Health Service, not whole-time applicable to dispensary doctors, but that the rea difficulty was in dealing with industrial areas. H pointed out that, in any communications with the Iris Public Health Council, the Irish Medical Committe had made it quite plain that it could not pledg the medical profession until it was first consulte as a body. A long discussion followed, which showe that there was a marked cleavage between the view of those engaged in dispensary practice and thos doing insurance work. Some of the speakers pointe out that the conditions had so altered since th report of the Viceregal Commission in 1906 that i could not be said now that the profession as a whol supported any National Health Service as applicabl me to Poor-law doctors. Undoubtedly, all were most xious to improve the condition of dispensary doctors, it was felt that a National Medical Service applicable hem alone was, in present circumstances, a misnomer. ose representing the insurance doctors pointed out it one-half of the total insured population of Ireland re in Ulster and one-fourth in Belfast, and they asked w the present dispensary doctors could attend to s vast body. Again, some of the audience were in our of the extension of medical treatment to the surance plan now in practice in Ireland, while others jected. Finally, it was unanimously agreed that the lfast medical profession could not commit themselves express any opinion until they had before them the mplete scheme promulgated by the Irish Public Health uncil, and a large committee, representative of every anch of the profession in Belfast, was appointed to conler the scheme when made public and to report back to neeting of the whole of the Belfast medical profession a future date.

Poor-law Salaries.

All over the country the Poor-law medical officers are owing much activity in pressing for increase of laries. The medical officers of the Castlecomer ion, having failed to receive the increases they ought fair, have given notice that they will refuse attend any patient, private or otherwise, until their mands are met. At a recent meeting of the medical en of the county and city of Kilkenny the following solution was passed:—

> 'That the initial salary for all dispensaries in the county lkenny be £300 per annum, with £5 annual increments until a aximum of £365 is reached, and to be retrospectively applied."

Ulster Medical Society.

A meeting of the Ulster Medical Society was held in e King Edward Memorial Hall of the Royal Victoria ospital on Jan. 29th, Mr. A. Fullerton, the President, the chair. The President introduced Major M. inclair, who gave a demonstration of his methods of eating fractures developed during the late war. The cturer fully explained the Thomas's splint, and owed how practically every injury of the extremities uld be treated by it, with various modifications to suit articular fractures. There was a crowded attendance f surgeons and general practitioners from the city and arrounding districts. At the close of the demonstraon Professor Thomas Sinclair proposed a vote of thanks the lecturer and said that he had, while acting as onsultant in France, utilised Major Sinclair's methods, nd had brought the surgeons working under him to ajor Sinclair's wards at Wimereux for instruction. He ommended the methods demonstrated that evening to he careful consideration of the practitioners in the north f Ireland, and hoped that future generations of medical tudents of the Belfast Medical School would continue o benefit by Major Sinclair's work.

Hospital Conditions in Belfast.

At the annual meeting of the Forster Green Hospital, elfast, held on Jan. 27th, it was reported that 202 ases were treated in this institution for consumption nd chest diseases during 1919. The corporation of elfast having now a sanatorium of their own for their ases, the Forster Green Hospital Committee has made new arrangement with the authorities of co. Down, o. Antrim, and co. Armagh for the admission of tuberulous patients. Unfortunately, the work of the institution was considerably interrupted in the second quarter f the past year owing to an outbreak of typhoid ever, due probably to an undiscovered "carrier," as o evidence of the origin of the epidemic could be iscovered. Financially, at the beginning of 1919 there as an adverse balance of £1942 10*s*. 11*d*., and this has ince been increased, by the extra expenditure entailed y the epidemic, to £2946 14*s*. 11*d*.

At the annual meeting of the Belfast Hospital for kin Diseases, held on Jan. 31st, it was reported that uring the past year 1035 patients have been treated. This institution was established in 1865, almost the irst hospital founded in the United Kingdom for the pecial treatment of skin diseases and allied conditions.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Malaria and Scabies in Vienna.

THE series of diseases under which the population of this city is suffering as a near or remote after-effect of the war has been augmented by an explosive appearance of scabies, which in peace time was rather scarce here. The trouble was so serious that extraordinary measures had to be adopted to control the outbreak. The population have no soap, cannot afford to bathe owing to the lack of fuel, and even the primitive laws of cleanliness are disregarded owing to the extreme poverty and the mass-accumulation of dwellers in slums. Therefore in some of the hospitals of the external districts arrangements have been made for a rapid "scabies cure," consisting in repeated applications of Wilkinson's ointment all over the body, followed by baths with coarse soap, the treatment lasting three hours. Meanwhile the garments are disinfected by hot steam. 300 patients can be dealt with daily in each hospital in that way. Another disease, formerly rare with us, now very frequent, is malaria. Large numbers of our soldiers stationed in Italy and the Balkans acquired malaria. A recent calculation showed that in Vienna alone over 27,000 cases were reported to the military authorities. A special malaria hospital has been established with a large staff of competent qualified medical men to do the special work, and the general practitioners have been warned of the possibility of malaria as an underlying cause of obscure diseases amongst the population. Chiefly subtertian and quartan forms have been noticed, mostly in men over 50, who were used as an army of occupation.

Decrease of Air Pollution from Lack of Coal.

A peculiar feature of the practical absence of coal-supply in Vienna is the change in the pollution of air by the products of combustion. In comparison with the results obtained in the laboratories of the meteorological offices in 1914 we find a decrease of more than 65 per cent. of soluble matter, whilst the insoluble matter decreased only by 40 per cent.—a sign of the inferior quality of the fuel now available. A large percentage of the factories are standing still, households get only a fraction of their former supply, and contamination by SO_2 is practically zero. The fogs often noticed here, which used to be pea-soup coloured, now have more the appearance of sea-fog. Perhaps the marked drop of acute nasal and bronchial affections which has been noticed is due to these changes in the air pollution. The out-patient departments of our nose and throat clinics are much less frequented than formerly.

Vital Statistics.

The report of the Burgomaster of Vienna on the health of this city, dealing with the year of 1919, is a most startling paper. It deals chiefly with the loss of population by the drop of birth-rate and excess of deaths over births. Already its effects are noticeable in the schools. The number of children in the first standard of all public schools amounted in 1910 to 36,000. Last year it was 25,469. This year (1920) it is only 23,000, and it will be less than 13,000 in four years. In 1910, the total sum of children in public schools was 242,386. In 1919 it fell to 195.748, and in four years it will drop, according to the laws of statistics, to 146,000. All this is due to the drop of the birth-rate. Worst still is the outlook as a consequence of the increase of mortality. Before the war the death-rate had come down from 36·2 per 1000 in 1871 to 15·3 per 1000 in 1913. In that year 32,314 persons died in Vienna. In 1918 51,497 persons died, amongst them 6000 succumbed to the grippe epidemic. 1919 showed a little better death-rate, but still 45,000 deaths were reported. A chief reason for the high mortality is the tuberculosis of the ages of 10–15 years. Whilst the death-rate of the infants is fairly stationary, it gradually increased from 22 per 1000 to 27 per 1000 for the ages of 2–5 years, increased further from the ages of 6–10 years, but it has more than doubled amongst the children of 10–15 years. The underfed children succumb more easily to the infections, and that is the real danger to this city, for in 1918 the excess mortality was 17,000, in 1919 32,000. Lately, also, the infant death-rate has begun to rise rapidly; it is now 15 per cent. of all infants under 1 year. Therefore, all endeavours have been made to obtain help—i.e., food and fuel—for the underfed children, and the noble gifts of foodstuffs distributed by the Society of Friends have been, and still are, a marked feature of help. Furthermore, the American Public Feeding Society of Vienna secures for all underfed children one meal daily, equivalent in its food value to one litre of standard cow's milk.

The Export of Children.

As soon as it was recognised that chronic starvation menaced the real backbone of the population—our children—efforts were made to get the neutral countries to invite large numbers of children for a few months of recuperation. Switzerland took the challenge up, Holland and the Scandinavian countries followed, and even Italy, the former enemy, at once invited—very generously and on a large scale—our children. At present about 30,000 children are constantly absent from Vienna; they accumulate strength and restore their shattered or half-starved anæmic bodies in the mild climate of Northern Italy, or in breezy Holland, or in the mountains of Switzerland. They stay there mostly three months, and then others take their turn. The Socialistic party of Italy, which is organising these transports with real magnanimity, is acting in a statesman-like way, which will bear good fruit in the future. The necessity of this movement is made manifest by a few figures. The American Feeding Society undertook a general examination of all children in the Vienna schools in December, 1919, and January, 1920. Of the 186,617 persons dealt with 96,789 were classified very badly underfed (Form 3), 63,402 badly underfed (Form 2), 19,694 underfed (Form 1); only 6732 were classified as being in good condition (less than 3 per cent. of the total). This disastrous condition is a real menace in case of an epidemic breaking out. No food, no fuel, no resistance—that is our present condition.

Jan. 23rd.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Ministry of Social Hygiene.

THE new Ministry of M. Millerand, in the course of reorganisation, has abolished the various Under Secretariats of State which had existed under the Ministry of War during the hostilities, and in particular has freed that of the Service de Santé, which reverts to its position in 1914 of the seventeenth department of the Ministry. Henceforward it will be under the control of the Medical Inspector-General, General Toubert. It was thought that this opportunity would be taken to establish the Ministry of Public Health, the formation of which has been so long discussed. But M. Millerand has preferred to create a Ministry of Social Hygiene, a new organisation with limits still ill-defined, at the head of which has been placed M. Breton, a non-medical deputy. However, M. Breton has shown much interest in science, and during the war was head of the Department of Inventions concerned with national defence. It was from this department that the French tanks emerged. The nucleus of origin of the new Ministry is constituted by the now abolished Department of Public Assistance and Hygiene, at the Ministry of the Interior. The scope of M. Breton's work is not yet known, nor if the Corps Médical will be to some extent under his jurisdiction. His first act has been to create a permanent commission to centralise efforts against depopulation. It is now eight years since a similar commission was established by the Minister of Finance; it has met on one occasion only.

Influenza.

Influenza has made rapid progress in Paris during the last week, but, though it is becoming widespread, it is certainly less serious than last year, and fatal pulmonary complications are comparatively ra Encephalitis lethargica does not appear to be creasing, but there is much diphtheria about Paris the moment.

The Employment of Red Cross Nurses in Infant Welfa Work.

The continued and progressive decrease in the Fren birth-rate provokes the appearance of numerous p jects and reforms, of which the majority are not ne One suggestion is that bounty money should be giv for every child after the fourth—a measure whi would be a heavy charge on the national budget, a which would not necessarily be efficacious. A mo practical method seeks to develop the child welfa movement. Indeed, the bounty would go mainly poor families among which, through ignorance of t way to bring up children, the infant mortality very high. Thus the money would often be spe with no ultimate benefit to the State. Statistics sh that in the working classes the infant mortality is 60 70 per cent., and this figure has hardly varied duri the last 30 years. Among the better classes, whe children are well cared for, the mortality is betwe 6 and 10 per cent. It is only recently that infant welfa centres, clinics, and "gouttes de laits" have begun develop, inspired by Budin and his pupils, by Vari and others. The effects are only slowly and partial becoming apparent as yet. A new impulse must no be given to the movement, and the best method providing this seems to be the organisation of help their own homes to all lying-in women througho the country. Such an organisation would enable t visitor to give the mother useful advice on bringing her child, and would show her how to get official assi ance at need in the form of milk, drugs, clothing, even money. To provide the necessary personnel this colossal undertaking M. Pecker, in the Departme of Seine et Oise, has called on the Red Cross nurs who are now unemployed. Lectures have sufficed teach them the special technical knowledge; these a necessary, as most of the nurses have been accustom to deal only with war wounds. M. Pecker is so w satisfied with the results obtained that he has ask the Union des Sociétés Françaises de la Croix-Rouge adopt the same plan for the rest of France. T President, Dr. Bouloumie, has consented, and it probable that this big scheme will be carried out.

Feb. 2nd.

ANTHRAX AND SHAVING BRUSHES.

A CASE of anthrax occurred recently in Norwich in whi it appeared likely that the infection was derived from shaving brush. The victim was a railway clerk, aged who was admitted to the isolation hospital on Jan. 6th wi a swelling of the left jaw. He said that a few days previous he had cut his face while shaving, and it felt as if he h cut off a pimple. The next day he felt as if a thorn w pricking him, and the place began to swell. He had be using a new shaving brush, which was purchased Norwich. He did not come in contact with animals in work. He died on Jan. 14th and at the inquest W. L. M. Goldie, resident medical officer at the isolati hospital, stated that the patient when admitted had swelling on the left jaw, which he removed. A cultu taken from this swelling showed the presence of anthr bacilli, but serum treatment was without effect. Po mortem a large hæmorrhage was found in the stoma and the kidneys were also affected. In Dr. Goldie's opini the cause of death was anthrax, but he was una to say how it was contracted. The shaving brush, havi been unsuccessfully examined for anthrax bacilli, w handed over to Dr. Cooper Pattin, the medical officer health, and by him forwarded to the Ministry of Healt The brush was one of a consignment marked "2594. Ma in Japan." The following report was received from t Ministry of Health: "Some brushes of the same pattern that used by the deceased—viz., 2594—were examined in o laboratories, and numerous anthrax colonies were found the culture." The evidence connecting the man's death wi an infected shaving brush is thus very suggestive.

Public Health.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

TWO REPORTS DEALING WITH TUBERCULOSIS.

County of Derby.

IN his annual report for 1918 Dr. Sidney Barwise akes some interesting comments on the tuberculosis oblem. He expresses the view that the only means "stamping out" the disease would be the discovery some form of vaccination against the malady. In e present state of our knowledge he advocates that tention should be directed to the child. It is well nown that, in the case of communities in which tuberulosis has not previously existed, its ravages are very reat when once it is introduced. It is probable, ndeed, that in this country we survive only because he bulk of the population have acquired immunity as result of slight attacks. The child is born without mmunity, and, if exposed to infection during the first ear of life, will almost certainly succumb. But under modern conditions it is impossible to avoid the ubiquitous ubercle bacillus, which, sooner or later, will almost nevitably gain access to the system. Early exposure o a strictly limited infection, together with the uilding up of resistance during the developmental eriod by making home and school conditions approximate as closely as possible to those of a sanatorium are, n Dr. Barwise's opinion, at present the best means at ur disposal for ensuring immunity. Infantile infecion mainly occurs through the mucous membrane of he upper respiratory passages or intestinal tract, probably more through the former channel than the atter. There is reason to believe that, massive direct nfection apart, most of the cases of tuberculosis in the adult are recrudescences and extensions of these early nfections, and would have been avoided if a high degree of immunity had been established and resistance raised to the utmost in childhood. If this be true, the hunt for "early adult" cases is, to some extent, based on an illusion, as the earliest diagnosable case in an adult is already probably many years old. It is obvious from the public health point of view that, the earlier cases are diagnosed, the sooner will the individuals concerned and their families come under the influence of the tuberculosis officer and begin to lead the "sanatorium life." At the present time the Public Health Department in Derbyshire fails to get into touch with the cases while they are in an early and curable stage. As many as 70 per cent. of the cases notified die within 12 weeks of notification.

In reference to the "after-care" of the consumptive, Dr. Barwise emphasises the fact that the term "farm colony" is often misunderstood. It does not, of course, imply that the tuberculous man or woman is to be engaged on farm work in the ordinary sense. Such work is skilled and heavy in character and necessitates a seven days' week. It could not be undertaken by the average phthisical person. By a "farm colony" is meant the housing of consumptives in detached houses, where forestry, nursery gardening, horticulture, fowl-keeping, woodwork, and similar handicrafts can be carried on, the products of their labour being sold through one organisation. A better term to employ would be "craft colony." In this connexion it will be necessary to come to an agreement with the labour organisations that certain industries shall be ear-marked as suitable for the consumptive, so that there shall be a good market for the products of his subsidised labour, and that he shall not be in direct competition with healthy labour. We must consider where the process of segregating consumptives is to end, and in order to get a true perspective of the problem we must remember that the great bulk of the population of these islands is suffering or has suffered from tuberculosis. The development of "craft colonies" will, it is hoped, meet the case of those patients whose occupations are obviously unsuitable or who are without occupation. It is a fact that no individual who has suffered from established pulmonary tuberculosis ever regains his full former working capacity. The extent of the loss sustained depends, other things being equal, on the strenuousness of the occupation, and on the physical effort involved. It may be observed that occupations requiring for their successful accomplishment prolonged exertion, even if completely "outdoor," are quite unsuitable for the post-tuberculous. It would be well if this loss of working capacity, and therefore of earning power, were generally recognised. A post-tuberculous subject may be capable of efficient and of brilliant and original work, especially when such work is of a skilled and technical nature; but in heavy manual work the consumptive cannot with impunity attempt to compete with the healthy. It is only just, therefore, that tuberculous subjects should be prepared to accept a lower wage, working shorter hours than the healthy; otherwise, in the coming days of high wages and corresponding high efficiency, it will be impossible to find them employment. This point has a definite bearing on the matter of the "minimum wage," now probably a permanent feature of industry, and Dr. Barwise commends the question to the sympathetic attention of the various trade-unions and other industrial organisations. He suggests that tuberculosis officers recognised by the Ministry of Health should certify the percentage efficiency of the consumptive, and that trade-unions should honour the certificates of these officers.

County Borough of Halifax.

The difficult problem of the after-care of the sanatorium patient is considered by Dr. James T. Neech in his annual report for the year 1918. While the term "after-care" savours, perhaps, too much of a belated policy, and resembles too closely the act of locking the stable door after the steed has been stolen, it would appear that, in the present state of our knowledge, some such procedure is absolutely necessary, and must occupy an important position in the campaign against tuberculosis. But the care of those who are strongly predisposed to the disease is probably an even more important problem. If "pre-care committees" were established for the purpose of securing good housing conditions and sanitary surroundings, healthy workshops, and suitable work for these unfortunate persons with a view to preventing the development of tuberculosis, much advantage to the public health would be likely to accrue. It is obvious that we shall never stamp out the malady by attempting to cure it, and the greatest hope for the future lies in the direction of prevention. In this connexion it is possible that we have, in the past, concentrated too much attention on the part played by the tubercle bacillus without having paid sufficient regard to the effect produced by other bacteria associated therewith in the gradual extension and progress of the disease. Mixed infections probably influence the course of many of the infectious diseases. In the case of diphtheria, for example, it has been noted that when mixed infections are present the administration of antitoxin is not followed by the marked benefit that generally results from its use. It has been shown by certain observers that the tubercle bacillus grows much more luxuriantly on nutrient media impregnated with the toxins of certain of the bacteria isolated from mixed infections. It is also well known that patients who suffer from broncho-pneumonia following measles or whooping-cough are often subsequently attacked by phthisis. The primary infections in these cases probably prepare the soil for the reception of the tubercle bacillus. Again, why does the tubercle bacillus remain more or less dormant and inactive within the body at times for long periods? May not this be due to absence of the necessary symbiotic influence during the phase of inactivity?

Whatever immunity may be, it seems to differ in its nature in different diseases, because in certain cases one attack confers almost absolute immunity against further attacks of the same disease, as in small-pox, for example; while in others one attack appears to predispose to further attacks of a similar nature. It is possible that immunity in phthisis consists to a great extent of immunity against the various bacteria usually associated with mixed infections. The tuberculous process is frequently a very chronic one, having perhaps lasted for years before the patient is brought under treatment at the sanatorium, yet a certain proportion of patients after admission show early signs of improvement, and it is such cases which usually obtain the greatest benefit from sanatorium treatment. It is difficult to believe that a few days' or even a few weeks' residence in a sanatorium can produce any marked modification in the tuberculous process per se. A chronic disease, unless it is maintained and intensified by a constantly recurring cause, which is more or less removable, would not be so modified. If the purely tuberculous process were so affected it appears probable that sanatorium treatment would be more successful than it has so far proved to be. In Dr. Neech's opinion, sanatorium treatment modifies the effects of the mixed or secondary infections rather than the tuberculous process itself. If this hypothesis be true it is worthy of careful consideration in connexion with the problem of prevention. The inhabitants of great industrial centres live, so to speak, on paved surfaces. This is necessary to prevent pollution of the soil and to facilitate cleansing, but such surfaces are readily dried, and any organic matter or any infective material cast thereon is readily converted into dust which is distributed by air-currents. The house affords a receptacle for the collection and retention of the infective agent or agents. The ventilation is often defective, and that, combined with the injurious influence of overheated rooms, tends to depress vitality. Where houses are crowded together in industrial areas there is a concentration of infection and polluted environment, with the result that the disease in such districts is more prevalent and destructive of life.

In Dr. Neech's opinion it is evident that the ultimate aim of after-care must be the removal of all known consumptives from populous centres into suitable country districts. Public opinion may not yet be ripe for compulsion in this matter, but a compulsory measure in some form will doubtless be necessary to place towns, in military parlance, "out of bounds to the consumptive." The suggested colony scheme with suitable factories, workshops, schools, &c., if properly organised, will undoubtedly serve a most useful purpose. But colonies alone will not suffice. Consumptive patients, as we all know, are among the most difficult to manage and many of them would object to go into colonies. If open-air treatment is to be more effectual in the future than it has been in the past, the method must be applied as a preventive agent, and those persons who are predisposed to the disease—namely, the families of the consumptives—must be given open-air treatment before and not after they have developed the disease. It will not be sufficient therefore, to transfer the consumptive only from congested areas; those who are markedly susceptible to the disease must also be removed into open-air surroundings. With this end in view Dr. Neech recommended his committee some two years ago[1] to erect a number of bungalows with open-air bedrooms for the accommodation of consumptive families, and he commends such a scheme to careful consideration, believing that it will command the approval of many who may object to the colony.

URBAN VITAL STATISTICS.

(Week ended Jan. 31st, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had declined from 16·2 to 15·3 in the four preceding weeks, rose to 15·9 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the annual death-rate was 16·8, or 1·7 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 4·9 in Oxford, 5·7 in Reading, and 7·0 in Willesden, to 21·7 in Merthyr Tydfil, 22·4 in Wolverhampton, and 23·0 in Liverpool and in Oldham. The principal epidemic diseases caused 400 deaths, which corresponded to an annual rate of 1·3 per 1000, and included 109 from measles, 100 from diphtheria, 96 from whooping-cough, 65 from infantile diarrhœa, 25 from scarlet fever, and 5 from enteric fever. Measles caused a death-rate of 1·8 in Leeds, 2·0 in Barrow-in-Furness and in Carlisle, 2·3 in Grimsby, and 4·4 in Barnsley; and whooping-cough of 1·4 in Leyton and in Norwich, and 1·6 in Birkenhe The 66 deaths from influenza were 19 less than the numb in the previous week, and included 15 in London, 7 Liverpool, and 6 each in Birmingham and Leeds. Th were 2550 cases of scarlet fever and 2008 of diphthe under treatment in the Metropolitan Asylums Hospit and the London Fever Hospital, against 2614 and 1 respectively at the end of the previous week. The cau of 43 deaths in the 96 towns were uncertified, of whi 13 were registered in Birmingham, 5 in Liverpool, and 3 [illegible] in Stoke-on-Trent and Manchester.

Scotch Towns.—In the 16 largest Scotch towns, with aggregate population estimated at 2,400,000 persons, t annual rate of mortality, which had been 16·6, 16·1, and 1 in the three preceding weeks, rose to 15·9 per 1000. T 340 deaths in Glasgow corresponded to [illegible] annual rate 15·9 per 1000, and included 3 from diphtheria, 2 from infant diarrhœa, and 1 each from measles and scarlet fever. T 102 deaths in Edinburgh were equal to [illegible] rate of 15·6 per 10 and included 2 each from measles and diphtheria.

Irish Towns—Jan. 24th.—The 156 deaths in Dublin cor sponded to an annual rate of 19·6, or 4·6 per 1000 above th recorded in the previous week, and included 2 from whoopin cough and 1 from diphtheria. The 141 deaths in Belfast we equal to [illegible] rate of 17·8 per 1000, and included 13 fro measles, 2 each from scarlet fever and diphtheria, and from whooping-cough.

Jan. 31st.—The 126 deaths in Dublin corresponded to annual rate of 15·8, or 3·8 per 1000 below that recorded the previous week, and included 4 from infantile diarrhœ and 1 each from enteric fever, scarlet fever, and whoopin cough. The 161 deaths in Belfast were equal to a rate 20·3 per 1000, and included 11 from measles, 6 from scarl fever, 2 from enteric fever, and 1 each from whooping-cou and infantile diarrhœa.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Temp. Surg. Lieut. D. H. Cameron transferred to pe manent list of Surgeon Lieutenants, R.N.

ARMY MEDICAL SERVICE.

Major-Gen. W. T. Swan retires on retired pay.

Lieut.-Col. J. P. J. Murphy is placed on the half-pay li on account of ill-health.

Major A. B. Hinde, retired pay, is granted the rank Lieutenant-Colonel on ceasing to be re-employed.

Capt. R. M. Dickson relinquishes the acting rank Lieutenant-Colonel.

To be acting Lieutenant-Colonels: Temp. Capt. (actir Major) G. W. Rea, Major and Bt. Lieut.-Col. B. A. Craig.

ROYAL ARMY MEDICAL CORPS.

Capt. R. O'Kelly relinquishes the acting rank of Lie tenant-Colonel.

Temp. Capt. J. F. O'Malley to be temporary Major.

The undermentioned relinquish the acting rank of Majo Capts. S. J. A. H. Walshe, A. G. Wells, E. G. S. Cane, E. Strachan, W. J. Tobin; Temp. Capts. A. S. K. Anderso W. J. Macdonald, B. H. Woodyatt, A. L. Robinson, H. Dummere, W. C. Sharpe.

To be acting Major: Capt. M. Morris.

Capt. E. G. H. Cowen retires, receiving a gratuity.

Lieut. (temp. Capt.) H. J. Bensted to be Captain.

T. W. J. Childs to be temporary Captain.

Officers relinquishing their services:—Temp. Lieut.-Co A. C. Suffern (and retains the rank of Lieutenant-Colonel Temp. Major (acting Lieut.-Col.) W. de M. Hill is grante the rank of Lieutenant-Colonel. Temporary Majors retain ing the rank of Major: W. P. Yetts, N. Roberts. Temporar Captains granted the rank of Major: J. W. C. Gunn, W. Macdonald. Temp. Capt. J. Howells. Temporary Captain retaining the rank of Captain: G. M. Cameron, E. H. Cameron J. R. Griffith, J. Geoghegan, B. M. Collard, T. E. George S. B. Radley, A. C. Lambert, R. O. Whyte, A. E. Moore T. V. Somerville (acting Major), G. J. C. Ferrier, R. H Stoddard, G. A. Lamont, F. H. Cooke, J. F. Hoare, A. H Huycke, F. T. D. Clindening, E. F. Wills, E. J. Peill, A. R Leggatte, J. P. McVey, C. Hunter, F. D. Parbury, A. L Martyn, J. D. Gimlette, E. Forbes, W. C. Morton, E. F Buckler, A. H. Wilson, E. A. Aylward, D. K. MacDougall A. G. Alexander, J. C. Anderson, G. N. Braham, C. Loddiges A. F. Miller, R. Crawford, E. R. C. Cooke, J. Gray, R. L Haines, K. D. Atteridge, D. I. Dakeyne, H. C. Martin D. Rees, R. C. Walker, D. S. Clarke, H. W. Perkins. Temp Lieut. F. G. McGuinness (retains the rank of Lieutenant) Temp. Hon. Lieut. C. H. Evans (retains the honorary rank of Lieutenant).

---

[1] THE LANCET, 1918, i., 416.

SPECIAL RESERVE OF OFFICERS.

apt. H. W. Hills relinquishes the acting rank of Major.

TERRITORIAL FORCE.

apt. F. Roberts is restored to the establishment.

ieut. P. W. G. Sargent to be Captain.

rd Southern General Hospital: Major L. M. Guilding is tored to the establishment.

st London Sanitary Company: Capt. A. G. Harrington estored to the establishment.

ITROUS OXIDE GAS FOR MILITARY HOSPITALS.

An Army Council Instruction states that supplies of trous oxide gas for military hospitals in the Eastern Command (except the counties of Middlesex, Kent, Surrey, and ssex and Woolwich District), Irish Command, Northern mmand, Scottish Command, Southern Command (except e counties of Buckingham, Berks, Dorset, Wilts, and ants), and Western Command, will be obtained from the ndensed Gas Company, 59–63, Grosvenor-street, Manester. Supplies of nitrous oxide gas for all other military spitals will be issued from Army Medical Store, Woolwich.

DEATHS IN THE SERVICES.

Lieutenant-Colonel Denis Francis Keegan, I.M.S., whose eath at the age of 80 was recently announced, qualified in 61 with the Membership of the Royal College of urgeons of England and graduated M.B. at the University of Dublin in 1862, proceeding to the M.D. degree ree years later. In 1866 he joined the Indian Medical ervice, and acted as residency surgeon, Indore, in 1877. e saw active service in the Afghan War of 1879–80 with ord Roberts, and was present at the battle of Kandahar, btaining the medal with clasp and the bronze star. In 881 he again became residency surgeon at Indore, and was ppointed civil medical officer for Central India. It was uring this period of his life that, following Biglow of merica, he practised and advocated litholapaxy for stone n the bladder and established that method in a firm posiion. He also did much original work in plastic surgery of he face, developing the operation known [illegible] Keegan's rhinolast. The preliminary result of his work in this direction vas published in Vol. I. of THE LANCET, 1891, p. 419. This vas afterwards expanded, and with many additions was ublished in book form in 1900 under the title of "Rhinoplastic Operations, with a Description of Recent mprovements in the Indian Method." For his services to urgery the Royal College of Surgeons of England conferred upon him in 1891 an honorary Fellowship. Colonel Keegan, who passed the later years of his life in Ireland, retired from the Indian Medical Service in 1894.

THE HONOURS LIST.

The following awards to medical men for valuable services rendered in or in connexion with military hospitals, territorial hospitals, war hospitals, auxiliary and civil hospitals, command depôts, convalescent camps, or on other duties of a similar nature in the United Kingdom in connexion with the army during the war, are announced:—

K.B.E.—Mr. J. F. Colyer.

C.B.E.—Dr. G. Blacker, Dr. C. Bolton, Dr. C. H. Bond, Dr. J. W. Carr, Dr. Helen Chambers, Dr. D. Drummond, Mr. E. P. Furber, Dr. Florence B. Lambert, Dr. H. Lett, Dr. T. Lewis, Dr. T. D. Lister, Dr. C. R. C. Lyster, Mr. L. H. McGavin, Dr. H. J. Paterson, Dr. J. Sinclair, Sir T. R. H. Smith, Bart., Dr. J. Taylor, Dr. R. A. Young.

O.B.E.—Lt.-Col. W. G. P. Alpin, Dr. W. D. Anderson, Mr. T. Baker, Dr. T. W. N. Barlow, Dr. J. H. Barnard, Dr. J. S. Boden, Mr. J. G. Boon, Dr. Winifred F. Buckley, Dr. W. F. R. Burgess, Mr. A. C. Burrows, Dr. C. T. T. Comber, Dr. R. Dagger, Dr. R. G. Davidson, Dr. W. H. Dickinson, Dr. L. G. Dillon, Dr. G. C. Garratt, Dr. H. W. Gell, Mr. T. P. Gostling, Mr. E. C. Greenwood, Mr. J. Z. Hanafy, Dr. A. Hawley, Dr. K. R. Hay, Mr. W. Hern, Dr. H. T. Herring, Dr. R. J. B. Howard, Dr. R. Humphreys, Mr. W. W. James, Dr. W. H. Jewell, Dr. H. J. Johnson, Mr. R. N. Jones, Mr. J. E. Kilvert, Mr. P. C. W. Laws, Mr. K. A. Lees, Dr. R. M. Hutchinson-Low, Dr. H. M. McCrea, Dr. N. McDonald, Dr. W. F. McEwen, Dr. Ethel M. Magill, Dr. C. J. L. Mansel, Maj. A. E. Morison, Dr. E. Moss, Dr. R. A. Murray, Mr. G. E. Newby, Mr. W. J. C. Nourse, Mr. J. I. Palmer, Mr. J. L. Payne, Dr. G. J. Peacocke, Dr. J. P. Philip, Dr. E. T. Pinhey, Dr. J. F. Porter, Mr. T. G. Prosser, Dr. J. A. Reed, Dr. P. J. Rendall, Dr. R. A. Rowlands, Dr. H. Sainsbury, Mr. O. B. Shelswell, Dr. Amy Sheppard, Dr. G. K. Smiley, Mr. J. A. Southern, Mr. G. S. Stansfield, Dr. R. de S. Stawell, Dr. H. W. M. Strover, Dr. E. G. Thomas, Dr. R. Turner, Dr. W. Turner, M.V.O., Mr. J. O. D. Wade, Mr. A. H. Warde, Dr. J. A. Wilson.

M.B.E.—Dr. T. C. Askin, Mr. R. T. Bailey, Dr. F. W. H. Bigley, Dr. W. T. Blackledge, Maj. J. F. Blood, Dr. E. M. Brockbank, Mr. T. W. Chaff, Dr. P. M. Chapman, Dr. A. C. Clarke, Dr. J. Craig, Dr. J. B. Cruickshank, Maj. G. H. Darwin, Mr. J. H. Fardon, Dr. C. H. Ferguson, Lieut.-Col. M. Gamble, Dr. C. F. Hadfield, Dr. J. Stirling-Hamilton, Capt. E. W. Hedley, Dr. G. E. Helme, Dr. J. B. Hughes, Mr. G. A. Hutchinson, Dr. Catherine M. Ironside, Dr. T. H. Jamieson, Dr. W. J. Lindsay, Dr. W. McClelland, Mr. G. MacGill, Dr. Mary C. Mackie, Mr. J. C. MacWatters, Dr. F. W. Melvin, Dr. W. S. Moore, Dr. J. G. Moyles, Mr. M. M. Murphy, Dr. H. T. Nixon, Dr. J. Noble, Dr. S. J. Palmer, Dr. W. H. Prentice, Mr. J. Rust, Dr. J. W. Stenhouse, Dr. J. S. B. Stopford, Prof. W. T. Thomas, Dr. T. H. Sanderson-Wells, Dr. H. B. Woodcock, Mr. F. W. Wilson, Dr. R. Wyse.

The Military Cross has been awarded to Temp. Capt. W. J. Maloney, R.A.M.C., for gallant and distinguished services in the field.

The following awards in recognition of valuable services rendered whilst prisoners of war or interned are announced:—

O.B.E.—Capt. T. W. Leighton, R.A.M.C. (T.F.); Maj. W. Mitchell, R.A.M.C.; Maj. F. S. Park, C.A.M.C.

M.B.E.—Asst. Surgs. E. B. Holt and H. A. T. Wells, I.M.D.

BROUGHT TO NOTICE.

The following have been brought to notice for gallant and distinguished services rendered in the field:—

Temp. Capt. I. C. Maclean, D.S.O., M.C., R.A.M.C. (died); Maj. F. S. Park, C.A.M.C.

Obituary.

HENRY LEWIS CLARE, M.D., B.CH. DUB., D.P.H. R.C.P.S. IREL.,

SURGEON-GENERAL AND CHIEF MEDICAL OFFICER OF HEALTH AND MEMBER OF THE LEGISLATIVE COUNCIL, TRINIDAD AND TOBAGO.

Dr. Henry Lewis Clare, who died on Jan. 24th at Bournemouth a few days before his sixty-fourth birthday, was a well-known officer of the West Indies Medical Service, and although he did not always see eye to eye with his authorities, he did useful work in the interests of public health.

Born in Dublin on Jan. 29th, 1858, he was educated at the Rathmines School and at Trinity College, graduating M.B., B.Ch. in the University in 1880. In the following year he was appointed junior resident medical officer of the public hospital at Kingston, Jamaica, and in the subsequent 14 years held appointments as medical officer for various districts in the Jamaica Medical Service. In 1896, the year in which he was President of the Jamaica branch of the British Medical Association, he was appointed district medical officer for Kingston and member of the Central Board of Health. After holding an appointment as acting superintendent medical officer for a year, in 1907 he became surgeon-general and chief medical officer of health for Trinidad and Tobago. While in this office he was involved in a conflict with the authorities. In 1910 a patient was admitted into the Colonial Hospital at Port of Spain and died within two days from bubonic plague. It was then alleged that the surgeon-general, who was also consulting surgeon to the hospital, though informed of the character of the case, had neglected to visit the patient, and did not declare the case to be one of plague until three days after death had occurred. A Commission was appointed by the Governor of the colony to inquire into this matter and other circumstances connected with the conduct of Dr. Clare's medical administration of the colony. This Commission sat for 27 days, and produced a report of 860 pages dealing in a most exhaustive manner with the whole question, but without finding that any of the serious allegations against the medical administration and personal character of Dr. Clare had been borne out. Certain failings in administrative capacity were, indeed, admitted by the chairman of the Commission, Mr. Justice A. D. Russell, but he found no proof of lack of honour or integrity, and congratulated the surgeon-general on having come so well out of an ordeal which wore many of the features of a persecution.

Dr. Clare acted as delegate from Trinidad to the Central Quarantine Authority at Barbadoes from 1908 to 1912, and was President of the first West Indies Inter-Colonial Conference on Tuberculosis, which was held at Port of Spain in March, 1913.

Correspondence.

"Audi alteram partem."

ŒDEMA AS A SYMPTOM IN SO-CALLED FOOD-DEFICIENCY DISEASES.

To the Editor of THE LANCET.

SIR,—Your issue of Jan. 31st contains an article with this title, from which it would appear that the author, Dr. A. Douglas Bigland, is not aware of the prevalence of "hunger œdema" in English Poor-law and insane institutions during the hard times in the winter of 1917–18. There must have been many cases and many deaths. These are firmly associated in my mind with deficiency of fat-soluble A; the calories were sufficient to sustain life, but the food had to be presented in the form of well-cooked soups, stews, or puddings, while fresh milk was in great deficiency. The cases were relieved here when the spring vegetables came into season, and definitely abolished later in the year by the fortunate purchase of 50 gallons of cod-liver oil, then almost unprocurable, and later on by the release of a special cheese ration by the Central Food Control. The symptoms bore no resemblance to those of pellagra, ot which I have seen two cases, or of scurvy, which latter disease used to be quite common in English asylums 25 years ago, before the necessity for a free supply of uncooked green vegetables was recognised, even although water-soluble C was then unknown. Beri-beri signs never occurred, but bread still contains a fair amount of water-soluble B.

Dr. Bigland hardly lays stress on either the mental dullness, which was an early sign, or the constant occurrence of the "scarlatinal or morbiliform rash." Really the spots are exactly like those of enteric on their first day, but appear mainly on the shins and dorsum of feet instead of the abdomen. The extreme loss of fat and moderate œdema with muscular asthenia and subnormal temperature were also typical. Naturally chronic dysenterics suffered badly, but not so much as the hard-working patients—e.g., stokers. Post mortem, the fat loculi were everywhere full of mucin-laden serum, and "œdema of the auriculo-ventricular junction" was universal. The adrenals were large and looked healthy, but a few cases of hæmorrhagic adrenalitis appeared.

At that time laboratory work was impossible owing to the absence of staff on war service, but the train of events seems fairly clear. Whatever the chemistry of vitamines and their interaction with the hormones may be, the adrenalin outflow was a protective sympathetico-tonus calculated to produce hyperglycæmia. Owing to starvation the effort was futile, consequently the depressive emotion as a muscle-sensory motor reaction scarcely occurred, and melancholics became less depressed. That cortical lipolysis was acute is evidenced by the mental dullness, and especially by the persistent residual dementia in many cases after physical recovery. There is considerable evidence that undue calcium katabolism and insufficient calcium intake are both susceptible to the influence of fat-soluble A, but it is not necessary to deal with these points at present.

I am, Sir, yours faithfully,

Cheddleton, Feb. 2nd, 1920. W. F. MENZIES.

THE INFECTIVITY OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I should like to reply to two points raised by Dr. H. Batty Shaw in his lecture on Pulmonary and Other Forms of Tuberculosis in your issue of Jan. 24th.

The failure of segregation.—It is true that sanatoriums and dispensaries are disappointing in the treatment of individual patients, but when Dr. Shaw goes on to infer that segregation and treatment of tuberculosis as an infective disease has failed, I cannot see any grounds for the inference. Tuberculosis is, indeed, notifiable, but no serious attempt has yet been made to treat it as an infective disease and isolate infective cases. Some may stay for a perio hospitals or sanatoriums, but for a short period not long enough for useful isolation; while, on other hand, general and special hospitals, Brompton itself, as Dr. Shaw points out, refuse and more to accommodate advanced and dange patients, who are therefore compelled to live " their own," and with disastrous results to their (at least in many instances that have come to notice). The meat of a cow with tuberculosis is allowed to be sold, but the milk is still sold; nothing whatever is done to deal with the far dangerous infective humans. It is almost as dangerous plague having attacked a certain commu the public health authorities of that community off free medicines to diseased patients and forbade a planes to fly over the infected area, but took no o precautions, and then complained that all measur segregation had failed.

The rôle of secondary infections.—It is also quite that those subject to bronchial and other respira catarrhs are more likely to develop tuberculosis others; but it does not follow that the second infecting organism is itself the dangerous factor. It just as well be that the secondary infection lowers local resistance to the tubercle bacillus and allows become more active. The latter hypothesis is likelier, perhaps, for the disposition to catarrhs usually lifelong, while the development of clin tuberculosis occurs later.

We await some further explanation of the m cases of clinical tuberculosis in which tubercle ba are not found in the sputum. There are doubtless so purely staphylococcal or pneumococcal infections wh simulate tuberculosis and account for a few, but many, of the cases in this group. Possibly so hitherto unrecognised form of the tubercle bacillus a spore stage will explain matters; certainly, elucidation of this problem is most important.

I am, Sir, yours faithfully,

Paignton, Jan. 27th, 1920. E. WARD

To the Editor of THE LANCET.

SIR,—In Dr. Batty Shaw's address in THE LANC of Jan. 24th tuberculosis is presented as a non-infectio disease, although the lectuer cites the fact that its perio city curve resembles that of the acute infectious diseas The difference appears to be merely one of chronic and not of infectivity. Infection by the tubercle bacill is universal amongst man. It is no support of t internal reinfection theory to say that in any particul individual a healed tuberculous lesion in a part may followed, after a lapse of months or years, by an acti lesion in another. If external reinfection takes pla in some cases—a concession Dr. Batty Shaw makes why should it not do so in all? Infections do n spread in a multiplicity of ways, and the better unde stood pathological processes become the simpler th are found to be. If the contentions in the address a correct, it is a needless and an alarmist policy advocate sputum flasks, separate bedrooms, separa eating utensils in cases of consumption. The reserv tions and small inconsistencies that crop up in th course of the address do not add to the strength of th argument.

Dr. Shaw deplores the undoubtedly poor results sanatorium treatment and the obvious failure of th antituberculosis measures in vogue, but he does n point out the cause of the failure. I wonder how man "homes for the dying" admit advanced tuberculo (consumptive) cases? As for the infirmaries, patien enter and leave these institutions as external circum stances dictate. The ultimate refuge of the consumptiv during his last months is, in the vast majority instances, his own, usually overcrowded, home. A fe years pass by, the family scatters, another membe develops the disease, but the direct connexion betwee the first case and the second is lost, and with it valuable detail. No observable source of massiv infection being found, the patient is supposed to hav inherited the disease in early childhood or even before he "inhuman and unsocial" procedure of segrega- in colonies was thoroughly carried out, the results d improve and tubercle in the span of a generation me as uncommon as leprosy. Surely it is logical olate those unfortunate members in our midst who become a source of danger to their neighbours. It ne in the acute infectious diseases, why not in the nic? Incidentally some figures which Dr. Shaw s support my contention—pessimistic though it be at once tubercle bacilli have appeared in the um the stage of cure is past. We have got into the t of thinking in days and weeks when dealing with ase so that the lapse of years makes us lose the between cause and effect. Rather let us be cruel e kind, than sit resignedly with folded arms and ly murmur "Kismet."

I am, Sir, yours faithfully,
OSCAR M. HOLDEN, M.D.
ansea, Jan. 28th, 1920.

HE INCREASE OF CRIMINAL ABORTION.

To the Editor of THE LANCET.

R,—Your leading article on criminal abortion raises e interesting and important points. Why should curing abortion for other than medical reasons be sidered a crime so grave that, in the opinion of a l-known judge of the High Court, the "professional rtionist," such as Gardner, ought to be hanged n he has the misfortune to lose a patient? I ress it thus because, as we all know, every abortion- iger, "professional" or occasional, does his best, what that may be worth, to keep his patient alive well: the last thing he desires is the illness or th of the woman concerned. So distinguished an hority as the late Dr. Mercier wrote: "The curing of abortion with the consent of the nan wrongs no one. ...... I can discover no nd reason in ethics for the great severity h which the procuring of abortion is punished law."[1] Is the reason adduced by the learned ge the main reason for this severity? Are not some the "other reasons" a good deal more important? he repeated induction of abortion is a heinous crime ause for our own safety as a nation we need "plenty children" "to meet our enemies in the gates" then at about the deliberate and intentional prevention of ception? If the "professional abortionist" ought be hanged, how about the Doctor of Science who pub- es details of procedures calculated to prevent con- tion? The influence of the latter in lowering the th-rate is probably a hundred times greater than that Gardner and Co., who at least practise in the semi- curity of back streets, while the publications referred are sold by thousands, probably tens of thousands, l certainly not by medical publishers to the profession ne.

suggest, Sir, that the main reason, and the most ensible, for severely punishing "criminal" abortion to protect the girl or woman from unfair suasion, ssure, or force on the part of lover, husband, or uaintances. If "criminal" abortion were not erely punishable every girl or woman who had the sfortune to become pregnant contrary to her own, r lover, or husband's desire, would be liable to s very undesirable form of pressure, and I fear re are a good many such persons who would t hesitate to exercise it. That this operation y possibly cause the death of the patient is in itself insufficient reason for banning it, because death y ensue from any "operation of election," if only m the anæsthetic; but the chances are that the risks artificial abortion would be entirely concealed from e patient.

In his list of offences against the racial principle . Mercier placed "criminal" abortion between fanticide and prevention of conception. "Infanticide, ocuring abortion, and preventing conception are anifestly three degrees of the same crime, and I ink manifestly diminish in turpitude from the first- entioned to the last."[2]

If purposive infanticide is never punished by death, why should accidental woman-slaughter be so severely punished, unless for the protection of woman against force and fraud on the part of her relatives, acquaintances, and advisers.

I am, Sir, yours faithfully,
BERESFORD KINGSFORD.
Upper George-street, W., Feb. 1st, 1920.

VACCINE TREATMENT OF ACUTE ORCHITIS AND CATARRHAL JAUNDICE.

To the Editor of THE LANCET.

SIR,—The following are personal experiences. During the last few years I have been specially unfortunate in my bacterial encounters, and it is in the hope that these may be of benefit to others that I venture to place them on record.

Nine years ago a very severe attack of nasal catarrh was followed by sinusitis. I sought relief in a warmer climate, but was attacked by left hemiplegia (fortunately not complete) in Venice, came straight home, and went to bed for six weeks. In the course of this time an attack of phlebitis developed in the left saphena, and in view of this I had no doubt that the hemiplegia was also of bacterial origin. With this idea I prepared an autogenous vaccine of *M. catarrhalis*, which was easily obtained from the nose, and this not only cured the general condition, but also the sinusitis and nasal catarrh. The hemiplegia disappeared completely.

Two and a half years ago, after five days of a severe attack of erysipelas, I became unconscious, and remained so for four days, when I regained consciousness with complete right hemiplegia and aphasia, being quite unable to articulate. Thanks to the kind care of my good friends, Dr. Percy Kidd and Dr. Porter Smith, I again made a rapid and complete recovery.

At Midsummer, 1918, a very severe attack of hæmaturia, lasting a week and followed by another on Dec. 1st, called for an investigation of the bladder, and was found to be due to a papilloma, which was dealt with by high-frequency current. The first operation gave rise to a good deal of cystitis, which I regarded as a natural consequence. On the second occasion pain began to be felt in the left inguinal canal 36 hours after the operation, and this passed down the cord, accompanied by swelling, first of the epididymis, and then of the testicle, which became greatly enlarged, but not, so far as I can judge, so tender as in gonorrhœal orchitis. After a day or two I noticed that the last few drops of urine were turbid, and taking advantage of this, I made a culture, which contained two organisms, a staphylococcus and a short stout bacillus. Without waiting to differentiate between the two, I made an autogenous vaccine, containing, as nearly as might be, 50 millions of each, as an initial dose. The general reaction after the second and following doses was very marked, a feeling of nausea, faintness, and general illness, lasting about three hours, but the effect upon the local conditions was most striking, since only six or seven doses in all were needed to effect a cure, though there is still a little fluid in the tunica vaginalis.

Two months ago, during a mild attack of nasal catarrh, I had a slight rigor, and a temperature of 99·6°F. on the first and second evenings. I continued to get about until the fifth day, when I noticed that the urine, though dark, remained clear on cooling. I then tested for bile, and, by barium chloride and chloroform, obtained enough pigment to give the reaction. Next day the conjunctivæ became yellow, and on the tenth day the fæces were quite white, and the general surface strongly pigmented. In view of the febrile attack I was led to suspect a bacterial infection, and having had catarrh at the onset, and having by me a dose of 1000 millions of my old autogenous vaccine, I injected it. The general reaction was much as above narrated. The nasal mucus yielded a pure and abundant growth of *M. catarrhalis*, and, to make a long story short, the bile returned to the fæces within four days, though it was five weeks before the urine and conjunctivæ became normal. I had in all six doses of the new vaccine. I should perhaps add that on neither occasion was any other treatment used after the vaccine was begun, so that in both it may fairly claim the credit.

---

[1] Crime and Criminals, p. 197.

[2] Ibid., p. 197.

In view of the attacks which have lately been made upon vaccine methods of treatment the above events are not without their lessons. Personally, it is my fixed rule never to prepare a vaccine for a patient without a reasonable chance of obtaining the peccant organism. For the same reason I always steadily decline to attempt the preparation of a blood vaccine except at the bedside. The sources of error are too many.

I am, Sir, yours faithfully,

E. C. BOUSFIELD, D.P.H. Camb. and Lond.,
Director, Camberwell Research Laboratories; Bacteriologist, Camberwell and Hackney.

ALIMENTARY TOXÆMIA.

To the Editor of THE LANCET.

SIR,—We may well give keen attention to the views suggested by Dr. R. Chetham-Strode and Dr. J. D. Benjafield in their recent communication (THE LANCET, Jan. 10th), for here we obtain a definite line of action based on a really scientific hypothesis, and controlled by tests which, though now somewhat haphazard, are of their nature not outside the possibility of proper control. Granted that the establishment of a lactic-acid fermentation within the large intestine is an essential foundation of health, it is clear that the directions as to diet, massage, autogenous vaccines, and the use of "sour-milk"—to which may well be added the wearing of a suitable abdominal support—offer what may well be a very fruitful field for therapeutic investigation; much must depend on the skill with which these things are made use of in combination or alone. One may hope, therefore, that the authors of the interesting communication in question will find time to collate the facts on which their lactic-fermentation view of health is founded. At the same time the busy practitioner will undoubtedly welcome some form of chemical test, readily applicable to the stools, that will enable him to know when this fermentation has become established, in place of the bacteriological index suggested.

I am, Sir, yours faithfully,

Harley-street, W., Jan. 31st, 1920. E. L. ASH, M.D.

LOCAL EFFECT OF QUININE INJECTION.

To the Editor of THE LANCET.

SIR,—An annotation on the Local Effect of Quinine Injection in THE LANCET of Jan. 31st concludes with the words, "the severe complications which may attend this practice would seem to contra-indicate it save under exceptional conditions."

I venture to think that the opinion thus expressed is misleading. In the actual treatment of malaria in Macedonia during three summers it was found that these severe complications were very exceptional, whereas the conditions necessitating intramuscular injection were, unfortunately, very common.

As one who saw some of Colonel L. S. Dudgeon's experimental results in the fresh state, I fully agree with his statements of the destructive effects of these injections. It is certain that every injection must cause a patch of necrosis in the muscle. I am equally certain, however, that the patient is none the worse. A few days' stiffness and slight local pain comprise all the ill-effects resulting from the injections, symptoms so slight that they should not be allowed to count against the therapeutic gain obtained by the extremely rapid absorption of the drug. This opinion is based on the observation of several hundred cases and on the personal experience of receiving a full course of injections myself, from which I have never felt the slightest ill-effects. Septic complications, and injuries to vessels and nerves, were in almost every case attributable to faulty technique, and were so rare in practice as to be almost negligible.

The consensus of clinical opinion in the Salonica Forces was certainly in favour of the free use of intramuscular injection as a means of obtaining a rapid control of the severe infections which were so common. I believe that for every case of permanent disabi from muscle or nerve injury produced by these in tions several lives were saved, and in consequen think that any statement which would tend to rest the use of this method of treatment in the sev forms of malaria is to be regretted.

I am, Sir, yours faithfully,

Welbeck-street, W., Feb. 3rd, 1920. HAROLD WILTSHIR

IS THERE A PARA-SCARLET FEVER?

To the Editor of THE LANCET.

SIR,—At the moment I have no wish to enter in discussion on what, in some instances, cases of r scarlet fever may or may not actually prove to be, there is a statement in Dr. Charles R. Box's lette your issue of Jan. 31st which puzzles me. In refer to mild scarlet fever cases he says: "One may sa once that none of the milder cases alluded to German measles; of this I am certain." For many years the diagnosis between scarlet fever rubella has interested me more than any other diagn For instance, I had learned that in some cases it impossible to differentiate, and I had also learned t the rash of rubella, from its start, occasionally imita the rash of scarlet fever. Dr. Box is certain th series of cases of supposed mild scarlet fever were n of them rubella, and he would confer a very gr benefit were he to indicate the points which shoul observed to make the differential diagnosis certain.

I am, Sir, yours faithfully,

FREDERIC THOMSON,
Medical Superintende
North-Eastern Hospital, Tottenham, N., Jan. 31st, 1920.

THE DEATH-ROLL OF STREET ACCIDENT

To the Editor of THE LANCET.

SIR,—We are so accustomed to reading of fatal st accidents, caused by taxi-cabs, motor, electric steam vehicles, and bicycles, and the verdict of coroner's court, "Accidental death—no blame attac to the driver," that in these days, when human lif held so cheaply, it is only when a relative or frien killed that we seriously consider what can be don prevent these accidents.

On putting together the statistics of the last (1 report of the Registrar-General (for the year 1917) find that in 12 months 1617 persons were killed England and Wales by these accidents; and m more would be seriously injured. Yet no one attem to commit suicide by placing him- or her-self in fron a taxi-cab or motor vehicle. In addition to accide through thoughtlessness and impatience, we h occasional risks through the drivers suffering f petit mal, epilepsy, syncopal attacks, and early gen paralysis. When the driver is clearly to blame h frequently dismissed with a short rebuke, as in typical instance in the north, where a lady was kil by a motor lorry on a bright afternoon. The dri admitted he was looking behind the lorry at the ti but the case was dismissed, with a rebuke from coroner, in terms less severe than most of us wo have used if our dog had been killed.

Some accidents are unavoidable, but much might done to prevent a large number of them; and m will agree with me that the time has arrived w Government should be again urged to enforce furt regulations with respect to motor traffic.

I am, Sir, yours faithfully,

Jan. 22nd, 1920. R. T. W

THE LATE MR. J. C. M'LACHLAN.—John Char M'Lachlan, L.R.C.P. & S. Edin., died on Jan. 18th, the age of 66. He received his medical education at University of Edinburgh and School of Medicine at Royal Colleges, qualifying in 1878. For more than 40 ye he was a well-known practitioner at Shelf, Halifax, a actively associated himself with the public life of district. He was medical officer for Shelf and part of Northowram union, a certifying factory surgeon, and member of the old school board. He was an antiquar and had an extensive knowledge of European cathedrals.

Medical News.

OYAL COLLEGE OF PHYSICIANS OF LONDON.—An inary Comitia was held on Jan. 29th, Sir Norman Moore, President, occupying the chair. The following were itted as Members: Dr. J. Beatty, Dr. T. I. Bennett, Dr. . Clarke, Dr. E. L. Collis, Dr. N. H. Fairley, Dr. Dorothy Hare, Dr. G. Marshall, Dr. S. G. Ross, Dr. K. Simpson, R. H. Simpson, Dr. A. T. Todd, Dr. Sibyl I. Welsh. ences to practise physic were granted to 65 candidates had conformed to the by-laws and regulations and sed the required examinations. ROYAL COLLEGES OF PHYSICIANS OF LONDON SURGEONS OF ENGLAND.—At the Final Examination, d from Jan. 13th to 27th, the following candidates were proved in the undermentioned subjects, but are not gible for diplomas:—

edicine.—S. E. Amos, St. Thomas's; Dorothy Bellows, Royal Free; Beryl Bolton, St. Mary's; J. P. Bonfield, Queen's Univ., Kingston, and London; T. A. Brown, Oxford and St. Thomas's; F. Christian, Univ. Coll.; Sarah Annie Cooper, Charing Cross; R. D. Cowan, Toronto and Middlesex; J. J. da Gama Machado, St. Bart.'s; S. N. Deboo, Bombay and London; K. H. Docuss, St. Bart.'s; E. E. Elt, Charing Cross; R. S. Fawssett, St. Bart.'s; J. O'F. Fletcher, St. Mary's; Agnes May Frew, Birmingham; E. E. D. Gray, Guy's; S. Grossman, Edinburgh; T. B. Hodgson, Oxford and St. Bart.'s; W. V. Hughes, St. Mary's; J. Kendall, Guy's; A. M. Kirdany, St. Bart.'s; G. V. C. Last, Liverpool; W. A. Low, St. Thomas's; E. Lowe, Birmingham; G. J. W. McMichael, Birmingham and Univ. Coll.; Cecily Margaret Evadne Maude, Royal Free; B. Molloy, Cork and Birmingham; L. Moss, Guy's; W. A. O'Connor, Oxford and Birmingham; F. R. Oliver, Cambridge and St. Bart.'s; H. C. Powell, Charing Cross; R. V. Powell, King's Coll.; R. F. Price, McGill; C. M. Probert, Guy's; J. Proujansky, London; I. M. Rattray, Cambridge and St. George's; T. Reed, Guy's; Esther Rickards, St. Mary's; E. L. Robert, Middlesex; Isabella McDougall Robertson, St. George's; E. T. Saravanamuttu, Madras and Edinburgh; Mary Selena Share-Jones, Liverpool and Manchester; J. A. P. Shaw, Cambridge and St. Thomas's; E. A. Sparks, St. Thomas's; F. D. Spencer, and G. C. Thornton, Birmingham; R. A. Walker, St. Thomas's; Lucy Wills, Royal Free; F. W. Zaglama, Manchester; and P. R. Zinn, New York.

Midwifery.—H. Amin, Guy's; Ivy Constance Beach, St. Mary's; A. Bearblock, Univ. Coll.; W. Beaumont, London; Dorothy Bellows, Royal Free; L. M. Billingham, St. Bart.'s; F. Blake, St. George's; C. H. Bracewell, St. Bart.'s; Hylda Catherine Briscoe and Mary Burfield, St. Mary's; C. L. C. Burns, St. Thomas's; A. Y. Cantin, London; G. W. Cheater, Charing Cross; D. Crawford, Cambridge and St. Bart.'s; F. W. Crook, Guy's; H. A. Crowther, Cambridge and Guy's; E. C. Curwen, Cambridge and St. Thomas's; K. V. Deakin, Manchester; M. A. Distaso, Cardiff and Bristol; A. H. G. Down, Univ. Coll.; T. A. J. Duff, Toronto; R. T. Edwards, London; E. E. Elt, Charing Cross; M. J. Erdberg, Durham; H. J. Ewart, Univ. Coll.; R. W. Fairfax, Charing Cross; R. A. Fanous, Manchester; R. K. Foulkes, King's Coll.; M. Garfield, Univ. Coll.; I. Griffiths, Liverpool; A. B. Hacking, Middlesex; Hilda Treloggen Haggett, Royal Free; C. K. J. Hamilton, Oxford and St. Thomas's; T. Handel, King's Coll.; Eleanor Harse, Royal Free; H. J. H. Hendley, Cambridge and St. Bart.'s; O. P. Hodge, Louisville; Florence Janetta Humphreys, Westminster; A. Y. Ibrahim, St. Thomas's; M. Jayakar, Univ. Coll.; Anna Keilin, Charing Cross; A. M. Khaleel, Middlesex; A. M. Kirdany, Cairo and St. Bart.'s; J. N. Laing, Manchester; F. Lawrence, London; J. H. Le Brasseur, Cambridge and St. Bart.'s; R. T. Lee, Sheffield; R. Lee-Michell, Middlesex; A. Leigh, Manchester; G. M. Lewis, Univ. Coll.; E. Lowe, Birmingham; Kathleen Maria Boyce McArthur, St. Mary's; R. A. McCabe, Middlesex; N. Makar, St. Thomas's; P. H. Marsden, Liverpool; B. Molloy, Cork and Birmingham; E. R. D. Nagel, St. Thomas's; C. W. Narbeth, St. Bart.'s; H. A. Nathan, Charing Cross; E. L. J. Nicole, Westminster; T. L. Ormerod, Oxford and St. Bart.'s; C. L. Pasricha, Cambridge and St. Bart.'s; R. M. Patterson, Guy's; E. F. Peck, Liverpool and St. Bart.'s; H. J. Phillips and J. Posner, Dublin; J. L. Potts, Cambridge and St. Bart's; H. C. Powell, Charing Cross; C. S. C. Prance, St. Bart.'s; Mary Colegrave Prideaux, St. Mary's; W. Remington, Guy's; M. H. Renall, St. Bart.'s; E. L. Robert, Middlesex; O. W. Robert's, King's Coll.; M. Rose, Guy's; E. Savage, St. Bart.'s; Katherine Jane Shaw, Royal Free; R. G. V. Shaw, Sydney and London; E. H. Strange, St. Bart.'s; H. J. V. Sutton, Middlesex; J. G. Tait, Edinburgh; J. McW. Taylor, Western Univ., Ont.; H. E. Thomas, Univ. Coll.; T. W. Turner, Guy's; J. van' Roojen, Amsterdam; A. R. Walker, Cambridge and St. Thomas's; R. P. Wanless, Durham Helena Jane Webster, Westminster; D. C. Williams, London; Lucy Wills, Royal Free; E. F. Wilson, Guy's; H. N. Witham, St. Thomas's; and C. F. Young, London.

Surgery.—W. G. Barnard, London; D. Crawford, Cambridge and St. Bart.'s; D. G. Garnett, Cambridge and St. Thomas's; R. R. Halsall, Manchester; F. Heber, London; W. V. Hughes, St. Mary's; D. Hunter, London; F. V. Jacques, Bristol and London; F. C. Jones and A. W. Kirkham, Manchester; P. T. Liang, Cambridge and St. Thomas's; H. Mackenzie, Queen's Univ., Kingston, and London; Esther Rickards, St. Mary's; C. Suffern, Cambridge and St. Thomas's; J. McW. Taylor, Western Univ., Ont.; M. Tree, London; and J. van Roojen, Amsterdam.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—G. R. Aspinwall (Sects. I. and II.), Cambridge and Guy's Hosp.; C. G. Bunn (Sects. I. and II.), Charing Cross Hosp.; N. D. Dunscombe (Sect. II.), Cambridge and St. Thomas's Hosp.; G. E. Rae (Sect. I.), Sheffield; and G. K. Reeves (Sects. I. and II.), Guy's Hosp.

Medicine.—J. G. Barrie (Sects. I. and II.), Guy's Hosp.; N. D. Dunscombe (Sect. II.), Cambridge and St. Thomas's Hosp.; A. H. El Rakshi (Sects. I. and II.), University Coll. Hosp.; J. Kendall (Sect. I.), Guy's Hospital; and W. E. Neale (Sect. I.), Bristol.

Forensic Medicine.—A. H. El Rakshi, Univ. Coll. Hosp.; and C. T. Gasking, Liverpool and Sheffield.

Midwifery.—A. H. El Rakshi, Univ. Coll. Hosp.; A. Keilin, Paris and Charing Cross Hosp.; and G. E. Rae, Sheffield.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: C. G. Bunn, N. D. Dunscombe, and G. K. Reeves.

Sir Archibald Garrod will deliver the Schorstein Memorial Lecture on Friday, Feb. 20th, at 4 P.M., in the anatomical theatre of the London Hospital Medical College, taking as his subject the Diagnosis of Disease of the Pancreas.

UNIVERSITY COLLEGE HOSPITAL UNITS.—Details of the formation of these units were given in our issue of last week. Every student is to take duty during his first year for two months' clerking and two months' dressing with the medical and surgical units respectively. Thus every student will in due course pass through both units.

UNIVERSITY OF MANCHESTER: CHAIR OF PHYSIOLOGY.—The Council has appointed Mr. A. V. Hill, O.B.E., M.A., F.R.S., to the chair of physiology, vacant through the resignation of Professor W. Stirling. Mr. Hill was a scholar of Trinity College, Cambridge, was third Wrangler in 1907, and was placed in the first class in Part II. of the Natural Science Tripos (Physiology) in 1909. He was George Henry Lewes student, Walsingham, Gedge, and Rolleston prizeman. In 1910 Mr. Hill was elected to a Fellowship at Trinity College, and in 1916 was elected a Fellow of King's College. In 1918 he became a Fellow of the Royal Society. During the war he obtained the rank of Major in the Cambridgeshire Regiment, and was appointed Director of the Anti-aircraft Experimental Section of the Munitions Invention Department. The inventions which he made proved of the greatest value in the scheme of defence against attack from the air. His researches on the physiology of voluntary muscle are recognised as pioneer work of the first importance.

DEATH OF DR. G. F. WELSFORD.—George Frederick Welsford, M.B. Cantab., M.R.C.S. Eng., who died at Tiverton on Jan. 21st, in his sixty-second year, was born in America of English parents, and educated at Clifton and Caius College, Cambridge, graduating B.A. at the University in 1880. After studying at St. Thomas's Hospital, where he was a keen student, he proceeded to the M.B. degree, and in the same year took the M.R.C.S. After qualifying he settled first in practice at Woodstock, but in 1891 he entered into partnership with Mr. C. E. Liesching at Tiverton, where he remained until his recent retirement from practice. On being appointed medical officer to the Tiverton Hospital he immediately took much interest in the institution, and was largely responsible for the building of pay wards and a modern operating theatre as a Diamond Jubilee Memorial to the late Queen Victoria. He was medical representative of the staff on the house committee of the hospital, and his services were in requisition in all questions that arose. He was also medical officer to the Tiverton Workhouse and to the Washfield Poor-law district. Of wide and varied reading, he associated himself readily with matters of interest affecting the public life of the country, and by educational lectures endeavoured to create local interest in health organisation. A quiet and reserved man, Welsford was the kindest and most considerate of friends and an interesting and amusing companion. During a long and trying illness he was attended by his second wife, who had been a trained nurse before her marriage, and much sympathy is felt for both her and her daughter, who had so little enjoyment out of the well-earned rest to which they were looking forward after Dr. Welsford's retirement from active work in June of last year.

Princess Helena Victoria will distribute badges to members of the League of the Roses at the Great Northern Central Hospital, Holloway, on Thursday afternoon, Feb. 12th, at 3 o'clock, and will be received by the Marquis of Northampton.

West London Medico-Chirurgical Society.—A pathological meeting will be held to-day, Friday, Feb. 6th, in the Society's rooms, West London Hospital. Specimens will be shown at 8 p.m. by Dr. J. M. Burnford, Lieutenant-Colonel McAdam Eccles, Dr. R. R. Elworthy, Dr. Reginald Morton, Dr. George Pernet, and Dr. H. J. F. Simson.

Medico-Psychological Association of Great Britain and Ireland.—The next quarterly meeting of this association will take place on Tuesday, Feb. 24th, at 11, Chandos-street, Cavendish-square, W., under the presidency of Dr. Bedford Pierce, at 2.45 p.m. Dr. Robert Hunter Steen, professor of psychological medicine, and physician to out-patients at King's College Hospital, will read a paper entitled "Chronic Hallucinatory Psychosis."

Literary Intelligence.—Messrs. Cassell and Co. announce for early publication a second edition, by Dr. Comyns Berkeley and Mr. Victor Bonney, of "A Text-book of Gynæcological Surgery." The book has been considerably expanded, and new illustrations, from drawings by Dr. Dupuy, have been inserted.—Messrs. J. and A. Churchill announce a new work entitled "A Laboratory Manual of Elementary Colloid Chemistry," by Mr. Emil Hatschek.

Royal Devon and Exeter Hospital.—The foundation stone of the new extension, the "Victory Wing," of this hospital was formally laid by Sir R. Newman, Bart., M.P., in the presence of a large gathering. The building is to be two storeys high, and will contain 100 new beds, thus enabling the hospital in future to accommodate 300 in-patients. The cost of the scheme is estimated at £35,000, and of this sum £23,000 have been already obtained.

Dorset Insurance Committee.—At the last meeting of the Dorset Insurance Committee it was reported that on Jan. 1st there were 75,603 insured persons. The average cost of each prescription for the half-year ending June last was 9·06*d*. A member having moved that in future the number of panel patients for each medical man should be limited to 1000, a medical member of the Committee remarked "with all respect they were talking about something they knew nothing about." It was reported that the average number of "panels" in Dorset was about 800. Eventually the proposition was defeated.

Royal Medical Benevolent Fund.—At the last meeting of the Case Committee held on Tuesday, Jan. 13th, 16 cases were considered and £224 10*s*. voted to 12 of the applicants. The following is a summary of some of the cases relieved:—

Daughter, aged 61, of M.R.C.S. Eng. who practised at Leatherhead and died in 1861. Until recently has been a school matron, and received from £30 to £40 a year. Now unable to obtain a post, owing chiefly to age and to the demobilisation of so many women. Voted £10.—Daughter, aged 47, of F.R.C.S. Irel. who practised in India and died in 1899. Has had a physical breakdown, after 15 years' rescue work in East London. Has a pension of £45, and receives about £4 from dividends, also £12 by teaching when possible. She also lets rooms, by which she earns about £30. Has a house in London, which brings her in £20 a year. Rates and taxes of London house, £26 10*s*.; rent of house in which she is now living, £43. Applicant has to support a friend who lives with her, and the weekly income works out at about 17*s*. to keep two. Voted £10.—Daughter, aged 43, of F.R.C.S. Irel. who practised in India and died in 1899. Sister of the above applicant. Has been doing rescue work for 12 years, but has been obliged to give it up owing to ill-health. She now lets rooms, from which she earns about £18. Receives pension of £45 and £2 from dividends. Rent 5*s*. for a cottage right in the country, and pumps own water and has no gas. Does own washing and attends to lodgers. Voted £10.—Daughter, aged 46, of M.R.C.S. Eng. who practised at Lincoln and died in 1908. Has no income, and is entirely dependent on her mother, who is an annuitant of the Fund. Rent 15*s*. for one room. Voted £12 in 12 instalments.—Daughter, aged 67, of L.R.C.S. Edin. who practised at Liverpool and died in 1893. Applicant lets rooms, from which she receives about £40. Has occasional help from another charity. Suffers from ill-health. Rent and rates, £26 2*s*. Cannot manage owing to the high cost of living. Relieved three times, £31. Voted £18 in 12 instalments.—Daughter, aged 67, of M.D. Edin. who practised in London and died in 1873. Applicant lives with two sisters, and they take in paying guests. Receives £48 from dividends and £30 from sister-in-law and £15 by teaching. Requires help towards paying coal bill. Relieved four times, £45. Voted £15.—Widow, aged 39, of M.R.C.S. Eng. who practised at Swansea and Liverpool and died in 1914. Has no income and is living with mother, whose income is limited. Has one daughter, aged 11, whom the Guild are helping to educate. Suffers from ill-health. Relieved five times, £60. Voted £12 in 12 instalments.—L.R.C.P. & S. Edin., aged 62, widower, who practised at Old Kirkpatrick. Receives £20 from another charity and £50 from his only son. Rent and taxes £28 10*s*. Suffers from ill-health. Relieved 15 times, £180. Voted £12 in 12 instalments.

Subscriptions may be sent to the honorary treasurer, Sir Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

Hospital Conditions in the Western Counti —A strong appeal has been issued by the Committee of South Devon and East Cornwall Hospital, Plymouth, increased financial support. It is estimated that at the clos the year there will be a deficit against the hospital of £700 The annual meeting of the subscribers to the Plymouth Infirmary was recently held. The medical report stated t 2106 patients had been treated during the past year and financial statement showed an unfavourable balance £400.—The Committee of the Royal United Hospital, Ba report that the total debt on this institution is £18,000.

No. 14 General Hospital, Wimereux: A Sta Dinner.—A dinner of the staff of this hospital was held at Victory Restaurant, Leicester-square, London, on Feb. 2 Sir John Goodwin, Director-General of the Army Med Service, and formerly commandant of the hospital, presid The company numbered about 100. General Sir Art Sloggett proposed the toast "No. 14 General Hospital," which General Sir John Goodwin responded. In the cou of the evening the following telegram was received from King in response to a message of loyal greeting:—

> I am commanded to express the thanks of the King to the s of No. 14 General Hospital, Wimereux, for their kind mess addressed to His Majesty on the occasion of the dinner, wh under the presidency of General Goodwin, their former and tinguished Commandant, has reunited that noble band of men women who ministered to the wounded and sick in one of largest hospitals in France. The King recalls with pleasure visit in October, 1915, to the Wimereux Hospital and recognises t the same spirit of devotion and comradeship which animated t work in those days has brought them together again this even His Majesty congratulates them on this happy reunion.

Some of the company had travelled from the North Scotland, France, and Belgium in order to be present.

The late Dr. G. Duffus.—George Duffus, w died at Woking on Jan. 18th, was a native of Cullen, wh he received his early education at the Free Church Sch He afterwards went to the University of Aberdeen, where passed a successful studentship, winning the gold medal materia medica and the Keith gold medal for practi surgery. After graduating M.B., C.M. in 1884 he beca assistant superintendent to the County Asylum, Macc field, and later superintendent of a private asylum n Liverpool, retiring from professional work about 15 years a Dr. Duffus was a benefactor to the poor of his native to in which he always took the keenest interest.

Death of Dr. D. Goyder.—David Goyder, ho rary physician to the Bradford Infirmary, died on Jan. 2 at Bradford in his ninety-first year. The son of a Swed borgian minister, he was born at Accrington in 1829, and the family moving to Glasgow was educated as a chem and obtained the diploma of the British Pharmaceuti Society. For a time he was engaged in his calling Ipswich, but returned to Glasgow, where he studied me cine at the University and graduated M.D. in 1860. the same year he became a licentiate of the Royal College Surgeons of Edinburgh. From 1862 to 1871 he was in partn ship at Bradford, afterwards practising as a consulta One of the founders in 1863 of the Bradford Medi Chirurgical Society, of which he was an ex-Preside having been honorary secretary for 25 years, he took active part in discussions and investigations into wo sorters' disease, and on resigning his position as secret was presented by his colleagues with his portrait in o He was President of the Bradford Philosophical Soci from 1901 to 1903.

Liverpool Infirmary for Children.—H.P. £90.

London County Council, Mental Hospital, Cane Hill, Coulsdon.—Asst. M.O. 7 gs. a week.

London County Council Mental Hospitals Service.—Fifth Asst. M.O.'s. £300.

Maidstone, West Kent General Hospital.—H.P. £200. Hon. Orthop. S. and M.O.

Manchester Children's Hospital, Pendlebury, near Manchester.—Res. M.O. £150.

Manchester Union.—M.O. £1000.

Margate, Royal Sea-Bathing Hospital for Surgical Tuberculosis.—Res. S. £200.

Merthyr Tydfil County Borough.—Female M.O. £500.

Newcastle-upon-Tyne and Northumberland Sanatorium for Consumptives, Barrasford, North Tyne.—Med. Supt. £500.

Newcastle-upon-Tyne, Hospital for Sick Children.—Junior Res. M.O. £200.

New Zealand, Auckland Hospital.—Bact. and Path. £900.

Northumberland County Council.—County M.O.H. and Sch. M.O. £800.

Norwich City.—Asst. M.O.H. £350.

Nottingham City Asylum, Mapperley Hill.—Sec. Asst. M.O. £400.

Nottingham General Hospital.—Hon. M.O. for X Ray and Electro-Therapeutic Dept.

Notts County Council.—Asst. Tuberc. O. and Asst. Sch. M.O. £500.

Queen Mary's Hospital for the East-End, Stratford, E.—Hon. Asst. P.'s. Res. M.O.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Res. M.O. £200.

Reading, Royal Berkshire Hospital.—Second H.S. £200.

Roxburgh County.—Asst. Tuberc. O. £450.

Royal Chest Hospital, City-road, E.C.—Res. M.O. and H.P. £200 and £120.

St. Bartholomew's Hospital and College.—Sen. Demonstr. of Physiology. £400.

St. Mary's Hospital, Paddington, W.—Clin. Asst. in X Rays Dept.

St. Thomas's Hospital, S.E.—Fellowship. £600.

Sheffield Royal Hospital.—Asst. Cas. O. £120.

Shrewsbury Borough.—M.O.H. £650.

South London Hospital for Women, South Side, Clapham, S.W.—Female Dental S. £25.

Southport General Infirmary.—Sen. H.S. £250.

Stoke-on-Trent.—Female M.O. £500.

Straits Settlements and Federated Malay States.—M.O.'s.

Sunderland County Borough.—Asst. M.O.H. and Maternity and Child Welfare M.O. £500.

University of London, South Kensington.—Examiners.

Wakefield, Clayton Hospital.—Jun. H.S. £150.

Whittingham, Preston, Lancs, County Asylum.—Asst. M.O. £300.

Wigan County Borough Education Committee.—Part-time School Dentist. £150.

Wigan Infirmary.—Junior H.S. £225.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Hatfield, Salford and Stretford, Shrewsbury, and at Long Melford.

Births, Marriages, and Deaths.

BIRTHS.

BURNHAM.—On Jan. 27th, at a nursing home, Birmingham, the wife of C. Burnham, M.B., Ch.B., F.R.C.S. Edin., of a daughter.

COMYN.—On Jan. 25th, at White House, Hythe, the wife of A. F. Comyn, M.B., of a daughter.

FITZMAURICE-KELLY.—On Jan. 27th, at Palmeira-mansions, Hove, the wife of Major M. Fitzmaurice-Kelly, R.A.M.C., of a daughter.

MCCALL.—On Jan. 27th, at Glenwood, Eltham-road, Lee, S.E., the wife of H. Dundas McCall, M.R.C.S., L.R.C.P., of a son.

SCOTT.—At The Terrace, Camberley, the wife of Major J. W. L. Scott, D.S.O., R.A.M.C., of a son.

VIVIAN.—On Jan. 25th, at Colden Manor, Twyford, Hants, the wife of C. St. A. Vivian, late Temporary Captain, R.A.M.C., of a daughter.

MARRIAGES.

STANGER—BIRKLEY-FORRESTER.—On Jan. 29th, at Fairford Church, Geoffrey Stanger, M.B., to Muriel, third daughter of the Rev. R. Birkley-Forrester and Mrs. Birkley-Forrester.

DEATHS.

BRETTINGHAM.—On Jan. 18th, at Christchurch-road, Bournemouth, Charles Edward Seppings Brettingham, L.R.F.P.S., D.P.H., &c.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, Feb. 12th.—Papers:—Mr. J. W. McBain and Mr. C. S. Salmon: Colloidal Electrolytes. Soap Solutions and their Constitution (communicated by Prof. S. Young).—Mr. C. C. Farr and Mr. D. B. Macleod: On the Viscosity of Sulphur (communicated by Dr. C. Chree).—Mr. C. V. Raman and Mr. B. Banerji: On Kaufman's Theory of the Impact of the Pianoforte Hammer (communicated by Dr. G. T. Walker, C.S.I.).—Commdr. T. Y. Baker, R.N., and Prof. L. N. G. Filon: On a Theory of the Second Order Longitudinal Spherical Aberration for a Symmetrical Optical System.—Dr. S. Chapman: A Note on Dr. Chree's Discussion of Two Magnetic Storms.—Dr. C. Chree: An Explanation of the Criticisms on Dr. Chapman's Recent Paper "An Outline of a Theory of Magnetic Storms.—Prof. J. W. Nicholson: The Lateral Vibrations of Sharply Pointed Bars.—Mr. R. E. Slade: A New Method of Spectrophotometry in the Visible and Ultra-Violet and the Absorption of Light by Silver Bromide (communicated by Sir Herbert Jackson, K.B.E.).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Feb. 10th.

OCCASIONAL LECTURE: at 5 P.M.

Professor A. D. Waller: The Measurement of Human Emotion and of its Voluntary Control.

MEETINGS OF SECTIONS.

Monday, Feb. 9th.

WAR (Hon. Secretaries—H. B. Hill, Oliver Robinson, J. McIntyre): at 5.30 P.M.

Discussion:

On "Gas Poisoning," to be opened by Sir Wilmot Herringham. Colonel Cummins, Dr. C. G. Douglas, Professor J. S. Haldane, and others will also speak.

Thursday, Feb. 12th.

BALNEOLOGY AND CLIMATOLOGY (Hon. Secretaries—J. Campbell McClure, C. F. Sonntag, F. G. Thomson): at 5.30 P.M.

Resumed Discussion:

On "The Merits and Defects of the British Health Resorts."

Dr. F. G. Thomson, Dr. J. Campbell McClure, and Dr. W. P. Kennedy will speak.

NEUROLOGY (Hon. Secretaries—P. W. Saunders, George Riddoch): at 8.30 P.M.

Paper:

Dr. Rows, C.B.E.: Anxiety States.

Friday, Feb. 13th.

CLINICAL (Hon. Secretaries—T. P. Legg, S. A. K. Wilson): at 5.30 P.M.

Cases (at 5 P.M.):

Will members who desire to show cases please communicate with one of the Hon. Secretaries?

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 9th.—8.30 P.M., Dr. H. Drinkwater: The Clinical or Naked Eye Diagnosis of Diphtheria and Other Infections of the Fauces (illustrated with the epidiascope, by coloured drawing and photographs).—Dr. T. B. Hyslop: On Some New Methods of Illustration (illustrated by the epidiascope).

BRITISH PSYCHOLOGICAL SOCIETY (EDUCATION SECTION), London Day Training College, Southampton-row, W.C.

Thursday, Feb. 12th.—6 P.M., Dr. C. W. Kimmins: The Dreams of Children in Blind, Deaf, and Industrial Schools.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday, Feb. 9th.—5 P.M., Hunterian Lecture:—Prof. H. T. Gray: The Influence of Nerve Impulses on Gastro-Intestinal Disorders—A Surgical Study.

Wednesday.—5 P.M., Hunterian Lecture:—Prof. J. Sherren, C.B.E.: The Late Results of the Surgical Treatment of Chronic Ulcers of the Stomach and Duodenum.

Friday.—5 P.M., Hunterian Lecture:—Prof. W. G. Spencer, O.B.E.: The Historical Relationship between Experiments on Animals and the Development of Surgery. Lecture I.

UNIVERSITY OF LONDON.

Advanced Lectures in Physiology to Students of the University and others interested in the subject.

A Course of Eight Lectures on Physiologically Balanced Solutions will be given by Dr. W. L. Symes in the Physiological Laboratory of the University, South Kensington, S.W.:—

Tuesday, Feb. 10th.—5 P.M., Lecture III.

A Course of Eight Lectures on the Reaction of the Blood and Acidosis will be given by Dr. J. W. Trevan, at St. Bartholomew's Hospital, West Smithfield, E.C.:—

Wednesday, Feb. 11th.—4.30 P.M., Lecture III.

A Course of Eight Lectures on the Regulation of Respiration will be given by Dr. M. S. Pembrey and Mr. J. H. Ryffel at Guy's Hospital, Borough, S.E.:—

Thursday, Feb. 12th.—4.30 P.M., Lecture VI.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON), Mile End, E.

A Course of Instruction on the Diseases of Children, open to Post-Graduates and to Students of the Hospital. (The lectures will be illustrated by lantern slides.)

Monday, Feb. 9th.—9.15 A.M., Lecture V.:—Dr. Thomps Organic and Functional Nervous Diseases, Meningitis Mental Deficiency. (At the Anatomical Theatre.)

Wednesday.—10 A.M., Clinical Demonstration:—Dr. Miller. the Children's Out-patient Department.)

Saturday.—10.15 A.M., Lecture VI., Dr. Hutchison: Gen Diseases. (At the Anatomical Theatre.)

NATIONAL HOSPITAL FOR DISEASES OF THE HEART PO GRADUATE COURSE, Westmoreland-street, W.

Monday, Feb. 9th.—11 A.M., Out-patients: Dr. Goodall. 2 P In-patients: Dr. Moon.

Tuesday.—2 P.M., Out-patients: Dr. R. Wells. 3 P.M., patients: Dr. Gibbes.

Wednesday.—2 P.M., Out-patients: Dr. Moon. 5.30 P Lecture:—Dr. Goodall: Heart Block.

Thursday.—10 A.M., In-patients: Dr. Hamill: 2 P.M., C patients: Dr. Price.

Friday.—2 P.M., Out-patients: Dr. Gibbes. 2.30 P.M., In-patien Dr. Wells.

Saturday.—10.30 A.M., In-patients: Dr. Hamill.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture H of the Institute, 37, Russell-square, W.C.

Special Course of Lectures and Demonstrations on Tuberculo for Medical Men and Women qualifying to become Tuber losis Officers, General Practitioners, and others. Bacteri gical Demonstrations will be given in the Laboratories of Institute, and visits arranged to Sanatoriums, Tuberculo Dispensaries, &c.

Thursday, Feb. 12th.—5 P.M., Lecture V.:—Dr. D. P. Sutherla The Work of a Tuberculosis Department.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Pri of Wales's General Hospital, Tottenham, N.

Tuesday, Feb. 10th.—2 P.M., Demonstration II.:—Mr. H. Carson: Hernia, with illustrative cases. 4.30 P.M., Lecture Dr. A. Giles: Some Gynæcological Fallacies.

NATIONAL HOSPITAL FOR THE PARALYSED AND E LEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, Feb. 9th.—2–3.30 P.M., Out-patient Clinic: Dr. Colli 3.30 P.M., Dr. Aldren Turner: Paraplegia. II.

Tuesday, Feb. 10th.—2–3.30 P.M., Out-patient Clinic: Dr. Grain Stewart. 3.30 P.M., Ward Cases: Dr. Risien Russell.

Wednesday, Feb. 11th.—2 P.M., Mr. Armour: Surgical Treatme of Cerebral Tumours. II. 3.30 P.M., Dr. Grainger Stewa Disseminated Sclerosis.

Thursday, Feb. 12th.—2–3.30 P.M., Out-patient Clinic: I Farquhar Buzzard. 3.30 P.M., Dr. Saunders: Progressi Muscular Atrophy.

Friday, Feb. 13th.—2–3.30 P.M., Out-patient Clinic: Dr. Gord Holmes. 3.30 P.M., Ward Cases: Dr. Tooth.

Saturday, Feb. 14th.—9 A.M., Surgical Operations.

Fee for Post-Graduate Course £7 7*s*. C. M. HINDS HOWELL, Dea

WEST LONDON POST-GRADUATE COLLEGE, West Lond Hospital, Hammersmith, W.

Saturday, Feb. 7th.—10 A.M., Dr. A. Saunders: Medical Diseas of Children.

Monday, Feb. 9th.—5 P.M., Mr. Addison: Appendicitis Children.

Tuesday.—5 P.M., Dr. Burnford: Clinical Lecture, with cases.

Wednesday.—5 P.M., Mr. Owen: Pneumothorax.

Thursday.—5 P.M., Dr. Simson: Uterine Fibroids.

Friday.—4.30 P.M., Special Lecture:—Mr. H. Groves: Bo Grafting in the Treatment of Fractures.

HOSPITAL FOR CONSUMPTION AND DISEASES OF TH CHEST, Brompton, S.W.

Wednesday, Feb. 11th.—4.30 P.M., Dr. Perkins: Demonstratio in the Wards.

ROYAL INSTITUTION OF GREAT BRITAIN, Albemarle-stree Piccadilly, W.

Tuesday, Feb. 10th.—3 P.M., Lecture:—Prof. G. E. Smith: Th Evolution of Man and the Early History of Civilisation. III The Search for Gold.

Thursday.—3 P.M., Prof. A. E. Conrady: Recent Progress i Applied Optics. (Lecture II.)

Friday.—9 P.M., Prof. W. M. Bayliss: The Volume of Blood an its Significance.

Saturday.—3 P.M., Sir Frank W. Dyson: The Astronomica Evidence bearing on Einstein's Theory of Gravitation: III Deflection of Light in the Sun's Gravitational Field.

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE POST GRADUATE DEMONSTRATIONS, at the Sheffield Roya Hospital.

Monday, Feb. 9th.—3.30 P.M., Dr. Nutt: X Ray Examination o Bones and Joints.

Tuesday.—4 P.M., Dr. Hay: Diseases of Conjunctiva.

Wednesday.—3.30 P.M., Dr. Wilkinson: Accessory Sinu Disease.

Thursday.—3.30 P.M., Dr. Skinner: Inflammations of Skin.

Friday.—4 P.M., Dr. Hay: Diseases of Cornea.

UNIVERSITY OF BIRMINGHAM—FACULTY OF MEDICINE in the Anatomical Theatre, Edmund-street, Birmingham.

Post-Graduate Course of Lectures on Venereal Disease:—

Wednesday, Feb. 11th.—4.15 P.M., Mr. B. Whitehouse: Gonor rhœa in the Female. (Lecture I.)

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC

Tuesday, Feb. 10th.—4.30 P.M., Practical Demonstration:—Loca Anæsthesia; Technique.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospital alternately.

Thursday, Feb. 12th.—4.30 P.M., Lecture:—Mr. Morley: Clinica Manifestations of the Mobile Cæcum. (At Ancoats Hospital.

otes, Short Comments, and Answers to Correspondents.

MAN'S ORIGIN.

By Professor G. Elliot Smith, M.D., F.R.C.P.

LECTURE on Man's Origin, the first of a series of three the Evolution of Man and the Early History of Civilisa- n, by Professor G. Elliot Smith, was given at the Royal stitution on Jan. 27th.

Man's Fossil Ancestors.

he first part of the lecture was occupied with reviewing palæontological evidence of the evolution of mankind. good deal of new evidence had been collected on this bject in the last 10 years, as a result of which the lecturer s able to show not only the stages of man's develop- ent, but the particular characters in his remote progenitors m which it had resulted. No remains of the human mily had been discovered in geological formations older an the early Pleistocene, but there was evidence from the iddle or early Pliocene period of a differentiation from the es. Incidental characters, though not themselves respon- le for development, are useful in proving the affinities of fferent genera. Such characteristics were demonstrated means of lantern-slide drawings of the transitional ages of jawbone from those of the Tarsioids to those of e modern Anthropoid apes. The resemblance of Tarsioid aracters to contemporary Lemuroids was also shown. though these were very striking, the lecturer pointed out at there were also certain differences to be observed, and at the features in which Tarsius differs from the con- mporary Lemur are the same features which show his finity with the primitive apes and with man. Thus arsius is so closely allied with the Lemuroids that the igin of the two from one undiscovered common stock is garded as certain, and the same animal, whose modern presentatives still inhabit the North American continent, hibit also the characters to which man owes his present premacy.

The Secret of Man's Success.

Pictures of the skull of Lemur and Tarsius were shown to lustrate their relative increase of brain capacity above at of the other mammals. The relationship of Lemur these latter is not yet known definitely, but a close lationship had been proven with certain of the shrews. he development of the brain was next called in as evidence the evolutionary process. Below mammals the dominant uiding sense is that of smell and the olfactory region of e brain occupies the dominant position. In the mam- al's brain sight, hearing, and touch are represented, s well as a motor area and an area for "discrimination." he brain of Tarsius showed a relatively huge visual area nd a rapidly diminishing olfactory area. The important volutionary changes in this brain were due to a flattening the face and to the forward-looking eyes, these two haracters resulting in binocular stereoscopic vision. The creased information which resulted from this new power roused curiosity, and so skilled movements of the hands ere called into play, the sense of touch developed, and a ew section of cerebral cortex to correlate the sense of touch ith that of vision. The mechanism of convergence also rovided information and assisted in the development of the rain. In the Lemuroids the projecting snout has prevented ll these developments, and an interesting contrast in intelli- ence is provided at the Zoo to all who will compare the ehaviour there of the lemurs with that of the anthropoid pes.

Man represents the straight line of development. It is the nimals which have departed from this straight line and or self-preservation have developed specialised characters e.g., the great strength of the gorilla), who have failed in he race for supremacy. Man has survived and become the reatest of the primates because of his faithful dependence pon the normally developing brain.

The Ethnological Munroe Doctrine.

On Feb. 3rd Professor Smith gave the second lecture of he series, entitled "Elephants and Ethnologists." It was levoted to a discussion of the earliest records of civilisation s found in the excavated monuments and codices of the ncient city of Copan, Honduras. There are two theories eld by ethnologists to account for the existence of this ivilisation, the earliest records of which date back to about 35 B.C. The one theory supposes that it sprang indigenously rom among the American aborigines, and the second that t was implanted by early voyagers across the Pacific. The irst theory is held by the majority of ethnologists at the present time, and especially by the Americans, who hold it as a kind of dogma—and it was this theory which Professor Smith set himself, most successfully, to explode. The influence of Eastern conventional art in the earliest drawings and sculpture of the West was proved by reference to the drawings and sculpture found in Copan and in Cambodia—the nearest point in the Malay Archipelago. All the traditions recorded in the ancient Sanskrit writings—the Vedas—find their counterpart in the earliest Western art. The elephant upon which the rain-god Indra was wont to ride is especially prominent, though American ethnologists have tried to explain away the appearance of this foreign animal in various unsatisfactory ways. Descriptions of a creature with "a nose so long that he can draw water from a well" are even found in the folk-lore of the North American Indians. It is impossible to summarise all the detailed argument. but all who listened to Professor Smith must agree that he thoroughly proved his case for the migration of civilisation westwards from the cradle of the race.

COLONIAL HEALTH REPORTS.

Ashanti.

IN a report by the Chief Commissioner for the year 1918 it is stated that the population, admittedly under-estimated at 287,814 in 1911, has increased since then. The European population in 1918 comprised 224 Government officials, 108 merchants, 102 miners, 7 missionaries, and 50 Syrians. Amongst Government officials there were 2 deaths and 24 invalidings, and among the miners 6 deaths and 8 invalidings. Five Syrian traders died from influenza.

There was a marked increase in the number of patients in the European Hospital, due largely, but not entirely, to an epidemic of influenza which swept over Coomassie in the month of October. The presence in Coomassie during the last three months of the year of an unusually large number of officers and British N.C.O.'s of the Gold Coast Regiment, who had returned from the East African campaign, many of them saturated with malaria, helped to swell the total. The health of the civilian Government officials continued fair notwithstanding the prolonged tours and increased duties demanded of them by the exigencies of the service. The health of the general European population was fair. There is evidence of the steadily increasing popularity of the Government native hospitals and of the increasing desire of the natives to avail themselves of the benefits of European treatment.

Influenza assumed a pandemic form in October and spread from Coomassie to all villages in the vicinity and also along the Ejura Road towards the Northern Territories. The onset was inevitable owing to the contagiousness of the disease and the impossibility of instituting effectual preventive measures in such a country. In Coomassie 381 natives, 5 Syrians, and 2 Europeans were registered as having died of influenza, but this by no means represents the real loss sustained by the community, as by far the greater portion of bodies was taken out of the town for burial and remained unregistered. The following is an approximate return of the deaths due to the scourge: Central Province, 4500; Western Province, 1500; Northern Province, 500; Southern Province, 2500; total, 9000.

The most prevalent diseases besides influenza were the same as in previous years, viz.: malaria, skin diseases, and diseases of the pulmonary and digestive systems. 2846 people were vaccinated—2264 successfully. The rainfall for the year was 61·96 inches at Coomassie, 67·17 at Obuasi, 71·73 at Kintampo, and 41·21 at Sunyani. The mean temperature was 74·95° at Coomassie, 78° at Obuasi, and 79° at Kintampo.

The climate is not suited for permanent European settlement. The average stay in the country is of 12 months' duration, after which recuperation in a more bracing climate is desirable

Northern Territories of the Gold Coast.

Mr. C. H. Armitage, Chief Commissioner, reporting on the affairs of these Territories for 1918, writes that there were no deaths among the European officials, but 80 were placed on the sick list during the year and 10 were invalided. All the invalidings but one occurred amongst the European officers and non-commissioned officers of the training centre which has been established at Tamale, and which has greatly increased the number of Europeans in the country.

The Census completed in 1911 gave an estimated population of 361,806 to the Northern Territories, with a computed area of 31,100 square miles—an average of 11·6 persons to the square mile. The Census returns for the Southern and North-Western Provinces were considered to be fairly accurate, but those of the North-Eastern Province fell far short of being correct, and it is estimated that not more than two-thirds of the inhabitants were enumerated. Systematic work continues to be carried on in order to render the next Census returns reliable in every respect. In spite of a heavy infant mortality it is considered that the population at the present day is greatly in excess of that shown in the last Census returns.

An outbreak of measles occurred in May at Bolgatanga, in the Zouaragu district of the North-Western Province, from which 425 deaths were reported, mainly among the children, who, owing to the shortage of food that then prevailed, were badly nourished and unable to withstand the attack. The North-Western Province suffered heavily from disease throughout the year. During the first quarter small-pox, which had broken out in 1917, was still rife in certain villages, and it was not until the second quarter that an adequate supply of lymph was sent up and vaccination was undertaken. This disappeared by the end of the quarter. 5687 natives were vaccinated in the Tumu District towards the end of the year by a French native vaccinator, who used serum prepared at Ougadougu by the French medical officer, which was kindly supplied through the good offices of the Resident at Leo. 140 children were inoculated at Tumu under the supervision of our medical officer, when only 8 of these showed no signs of the serum having taken. Many more people could have been vaccinated had not the natives been prostrated by influenza when the vaccinator's services were available.

In March a mysterious disease, afterwards diagnosed as anthrax, made its appearance in the Lorha District and was accountable for a number of deaths. In October the whole province was swept by influenza, which levied a heavy toll on the unfortunate natives. There is reason to believe that the following figures, obtained from the chiefs and headmen, greatly under-estimate the mortality that occurred: Southern Province, 2517; North-Eastern Province, 18,267; North-Western Province, 7880; total, 28,664. It is thought that the high mortality in the North-Eastern Province was due to the lack of clothing worn by the natives. Another feature of the epidemic was that it seemed to pass by the old and decrepit of both sexes and to select its victims from among the young and robust.

Leprosy is not on the increase and, while uncommon in the Southern and North-Western Provinces, is of more frequent occurrence in the North-Eastern Province. The natives look upon it as "a visitation of Allah," but say that it shows no signs of spreading and are generally averse to compulsory isolation.

The climate of the Northern Territories, while similar to that of the Gold Coast and Ashanti, may be said in comparison with them to be more trying in its extremes. It possesses an insidious quality that lowers the vitality of Europeans and renders unduly prolonged residence on their part inadvisable, and it is generally recognised that a period of recuperation in a more bracing and salubrious climate is necessary after a year's stay in the country.

A VOCAL THERAPY SOCIETY.

CURATIVE singing, to which allusion has recently been made in the public press, is a well-established treatment, training in singing having proved to be valuable, not only for the development of deficient breathing and the relief of loss of voice by stammering, but also by helping in the recovery of memory. The exhilarating effect of vocal efforts have resulted in a gain of mental and physical control. An earnest appeal for subscriptions to support and organise this form of treatment has been issued by Sir Bryan Donkin, chairman of the Vocal Therapy Fund, and the Dowager Countess of Carnarvon, vice-chairman, and replies should be made to the honorary treasurer, H. E. Bury, Esq., 47, Lincoln's Inn Fields, London, W.C. 2, or the honorary secretary, 32, Charles-street, Mayfair, W. 1.

"GREY POWDERS."

RECENTLY, at Exeter, a druggist was summoned for selling to the sanitary inspector, "grey powders," which were not of the substance demanded. It was stated that the powders contained calomel with other ingredients, and not the mercury and chalk of the official Pharmacopœia preparation. For the defence it was stated that the firm had been selling "a grey powder" since 1868; it was a preparation of their own and grey in colour. A magistrate remarked that *before* 1898 only Latin descriptions were used in the Pharmacopœia, and consequently the term "grey powder" was not mentioned. For the defence it was contended that six grey powders had been purchased as one article, and only one powder had been analysed, whereas the whole six powders should have been examined. The bench of magistrates upheld this view, and the case was dismissed. The deputy town clerk remarked that the local authority had obtained their object in ventilating the case. The public danger indicated by the defence is a little startling.

A MYXŒDEMATOUS ARTIST.

To the Editor of THE LANCET.

SIR,—Dr. H. Crichton Miller, in his paper on the Endocrine Glands in Mental Disorder read before the Royal Society of Medicine and reported in THE LANCET of Jan. 24th last, asks "Who has ever conceived of a myxœdematous artist?" It is true the case was not one of myxœdema, but since this and cretinism are both due to hypothyroidism Dr. Miller may be interested to know that a *cretin imbecile*, named Gottfried Mind, who was born in Berne in 1768 and who died at the age of 46 years, acquired such a reputation as an artist as to be known as "The Cat's Raphael." He is referred to in my book on "Mental Deficiency" under "Idiots Savants."

I am, Sir, yours faithfully,

Jan. 27th, 1920. A. F. TREDGOLD, M.D.

AN INTERESTING ETYMOLOGY.

To the Editor of THE LANCET.

SIR,—For many years I have seen the name "Stovaine" referred to in medical literature, and have also seen the name in medical dictionaries without any etymology. Last week, when wishing to discover whether the word had a final "e," I consulted Dorland's Medical Dictionary, last edition, and found this interesting addition: "Named for the discoverer, Fourneau, which is French for 'stove.'" Being interested in etymology, I thereupon wrote to Messrs. Poulenc Frères, of Paris, to confirm this, and their reply, dated Jan. 15th, should, it seems to me, be preserved. The translation is as follows.

"The etymology given by the American dictionary of 'stovai is perfectly correct. At the time of the baptism of the new lo anæsthetic, which first saw the light in our laboratories, we wisl to introduce into the fancy name which should designate it name of the discoverer, M. Fourneau. As it was impossible create a euphonic word in French with this name, we took English translation of the common corresponding name, which l itself marvellously to this purpose. M. Fourneau has been several years the head of our research laboratories. While rema ing our technical adviser, he is now professor of chemiotherapy the Pasteur Institute and a member of the Academy of Medicine

Future students might be grateful for this information.

I am, Sir, yours faithfully,

Jan. 19th, 1920. W

THE MEMBERS OF PENSIONS BOARDS.

To the Editor of THE LANCET.

SIR,—Surely there is something very far wrong wh doctors with enormous panel lists of 3000 and 4000 c afford to spend so much of their time officiating on t medical pensions boards. Is it at all reasonable to expe that these men can be doing their duty to their pan patients and be able to spend forenoon and afternoon f three, four, and five days a week away from their practice Many of us now struggling to build up again the practic we sacrificed have to compete on even, and less than eve terms with these men, while many of them stayed at hon and obtained the job when we were on active service.

I am, Sir, yours faithfully,

Jan. 28th, 1920. EX-R.A.M.C.

*** We hope that there are not many practitioner whether on or off the pensions boards, who conduct in vidually such panel practices.—ED. L.

Hunterian Oration

ON

BLOOD VESSELS AND PRESSURE.

Delivered before the Hunterian Society on Jan. 14th, 1920,

BY LEONARD HILL, M.B. LOND., F.R.S.,
DIRECTOR, DEPARTMENT OF APPLIED PHYSIOLOGY, MEDICAL RESEARCH COMMITTEE.

GENTLEMEN,—Professor Arthur Keith, in his admirable address to this Society, relieved me of part of my proposed exposition by setting forth the views held by Hunter concerning the arteries, their contractility and living sensitive nature, and the call of the living tissues for blood which determines the circulation.. I therefore propose to lay before you this evening those principles of the circulation which appear essential to me, and which are based on evidence published in a number of papers hitherto not summarised. Before so doing I venture to assume the powers of Prospero and summon the spirit of Hunter from the vasty deep to be present with us this evening and critically consider a line of research which, so far as conducted in the Hunterian method of inquiry, is homage to the master.

INQUIRY INTO THE PRINCIPLES OF THE CEREBRAL CIRCULATION.

This research began a quarter of a century ago with an inquiry into the principles of the cerebral circulation.

I start with the measurement of the pressure of the brain against the skull wall, as shown in Fig. 1. *a* is a tube closed by a thin rubber membrane screwed into a trephine hole, *b* an air-bubble index, *d* a pressure bottle, *c* a manometer. The bulging brain presses the index out, it is restored to zero position by raising the pressure bottle, and the manometer records the required pressure. Trephining the lamina of the atlas, the same method gave me the pressure of the cerebro-spinal fluid. Trephining the torcular herophili, a bony cavity, in the dog, the cerebral venous pressure was recorded. All three pressures were the same, all three indices showed similar cardiac pulsations and respiratory oscillations of pressure. In the morphinised dog, lying horizontal, the pressures were about 5–10 mm. Hg. If the belly were squeezed the three pressures rose together and equally, if the heart stopped they fell together to zero. The three pressures could be made to rise together by raising the pressure in the aorta or in the venæ cavæ. They could be raised by allowing normal saline to run into the cerebro-spinal cavity at a somewhat greater pressure. They signify that part of the arterial pressure which, left over after the resistance is overcome, expands the brain—i.e., the capillary-venous pressure.

The expansion of the cerebral arteries at each pulse helps to expel blood out of the brain into the venous sinuses, the inspiratory rise of arterial pressure also usually expands the brain, but the expiratory rise of venous pressure, if this be increased, may expand it more, as may be seen in the fontanelle of the crying infant.

Suppose a foreign body is introduced into the skull—e.g., a brass tube, with rubber bag attached, screwed into a trephine hole, and the bag blown out by a measured amount of water (a depressed fracture or blood extravasated from a meningeal artery acts in the same way), the bag expresses blood out of the surrounding brain, and the pressure in the obstructed vessels rises to the arterial pressure. The foreign body, blood clot, or depressed bone does not continue to press, but merely occupies room. It has ensanguined a part of the brain, and so raised the circulatory pressure in ádjoining parts. Removal of the clot or bone is the remedy.

Consider next an inflamed area of the brain; the bacterial toxin causes dilation of the arteries, and there is increased imbibition of fluid by the poisoned tissues, the circulatory pressure rises then in the inflamed part, and the contiguous parts are pressed upon and partly exsanguined by the swollen part. So, too, in the case of a tumour; the fast-growing tumour with larger vessels swells at the expense of the other parts which become partly exsanguined.

Compensation for the room taken in the above ways may be brought about naturally by removal of tissue substance (by way of the circulation) out of the skull cavity. The skull is a rigid case, and its contents cannot vary so long as the skull is closed, but there may be more blood in the brain and less cerebro-spinal fluid or tissue substance, or on the other hand less blood and more fluid or tissue substance. The arteries may dilate and the tissue cells swell and confine the size of the veins so that there is a relatively rapid flow through the capillaries, or the arteries and cells may shrink and the veins dilate so that there is congestion with sluggish flow. But swelling and shrinking of tissue cells takes time. In the case of a rapid fall of circulatory pressure—i.e., if the heart be stopped—the brain does not shrink away from a glass window screwed into the skull, while it does shrink and empty of blood if air be admitted into the skull.

Given a normal level of arterial and vena cava pressures, the circulatory pressure in the brain is ruled by the swelling of the brain cells and by the secretion of cerebro-spinal fluid by the cells of the choroidal fringes, the degree of swelling and the volume of fluid together regulating the lumen of the veins, and so the capillary venous pressure. In a healthy state of activity the cerebral arteries are moderately expanded, the tissue cells in a normal state of turgescence, the veins narrow, the flow of blood and oxygenation good. In a state of collapse the opposite conditions hold, arterial pressure is low, veins congested, the blood flow slow, oxygenation poor. In the infant collapsed from diarrhœa the fontanelle is drawn in; it expands in the inverted position of the child.

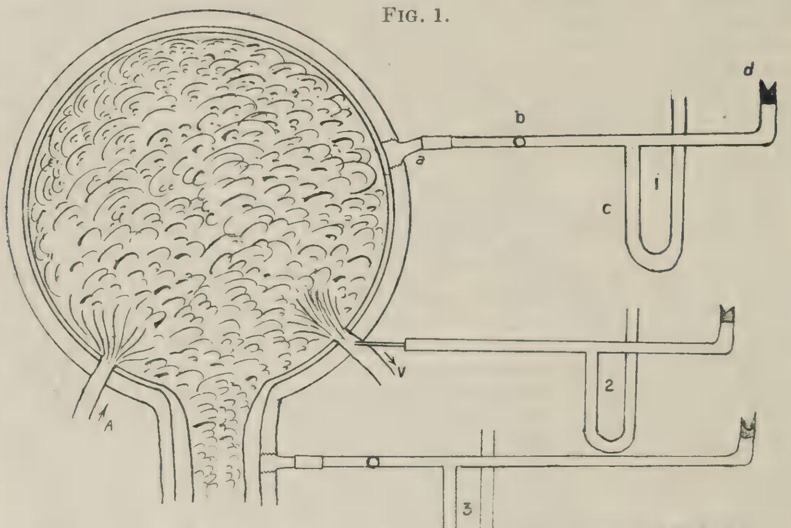
EFFECT OF GRAVITY ON THE CIRCULATION.

Consider the model Fig 2. *A* and *B* are the thin-walled rubber bags. The whole is affixed to a board, and the "heart" rhythmically pulsed and filled with water to a slight degree of distension while in the horizontal position. On placing the board vertical, *A* and the "heart" empty and *B* fills, owing to the hydrostatic pressure of the water and the expansile nature of the rubber bag. Give *A* a rigid case, make it non-collapsible, like the brain within the skull, the circulation in *A* will cease in the vertical position, if the "heart" does not fill, though *A* does not empty of blood. Squeeze *B* and the "heart" fills and the circulation begins again.

I took a grass-snake and fixed it lengthwise to a board, and exposed its heart and some inch of the vena cava below the heart. I put the board vertical with the head uppermost, the heart became empty the blood standing at a lower level in the vena cava. I lowered the board, the heart filled, and the circulation began again. I put the board vertical once more and squeezed the body upwards, the heart filled; again I let go, and the heart emptied. Next, keeping the board vertical, I sank it in a bath of water, the hydrostatic pressure of the water outside balanced that of the blood within—not fully, because the skin resists the water, but enough for the heart to fill. I then put the board vertical with the head downwards, the heart filled, but the pericardium resisted over-distension, acting as the leather case does to a football bladder. I incised the pericardium, and the heart bulged through the opening. I removed the pericardium wholly, and the heart swelled greatly and could scarcely empty itself.

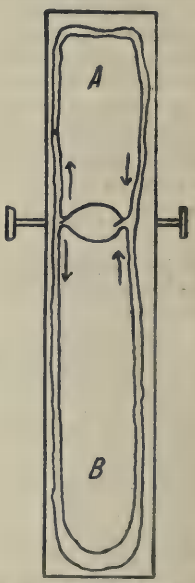
I repeated these experiments on eels. The pericardium protected the heart of the eel from the compressive action of its muscles, which otherwise produced over-distension when the animal struggled.

FIG. 1.



Schema of experiment designed to measure the pressure of the brain. At (1) the gauge is applied through a trephine hole in the skull-wall, at (2) through the lamina of the atlas, at (3) in the torcular herophili. A = artery, V = vein. (For other lettering see text).

FIG. 2.



Model to show the effect of gravity on the circulation.

I took a hutch rabbit, a big-bellied one used to over-feeding and an indolent life; I fixed it to a board with head and limbs outstretched, and placed it in the vertical position with head uppermost. After a few minutes the ears and lips began to blanch, and in spite of expiratory struggles which temporarily restored the circulation, the heart ceased to fill, the cerebral circulation failed, the pupil became insensitive to light, the cornea to touch, and the breathing stopped. On restoring the animal to the horizontal position consciousness returned again. If while in the vertical posture the belly were squeezed, consciousness was equally restored. So, too, if the animal were sunk in a bath. In the vertical posture the heart was found to be empty, the blood standing in the vena cava at a level below the heart, the vena cava drawn taut by the viscera hanging on it. On compressing the belly the blood could be watched filling the vena cava inferior and right side of the heart. Repeating the experiment on a wild rabbit with firm belly wall, nothing happened; the heart did not empty, the cerebral circulation continued.

In the cat or dog the carotid blood pressure is well maintained in the vertical position, but poisoning with chloroform, or division of the spinal cord in the upper thoracic region, brings about a great fall by weakening the vaso-motor control and the support of the abdominal muscles.

The invention by the late Harold Barnard and myself[1] of the armlet for blood-pressure measurement enabled me to measure the influence of gravity on the circulation in man. I found that in the standing posture the pressure in the posterior tibial artery was higher than in the brachial by the height of the column of blood between them. In normal recumbent young men they were the same. In the inverted position (head down) the pressure in the leg artery was lower than that in the arm artery by the height of the column of blood which separated them, but be it noted the pressure in the brachial was the same in all three postures. The circulatory mechanism is so contrived as to keep the blood pressure constant in the ascending aorta, while that in the legs varies with posture very widely. Engaged in this mechanism are afferent nerves, which supply the mouths of the venæ cavæ and the root of the aorta and reflexly control the frequency of the heart and the contraction of the arteries. The tone of the belly muscles and the respiratory pump is also influenced reflexly by the weight of the organs acting on afferent nerve endings and by the flow of blood through the nerve centres and oxygenation of these. In the case of a convalescent, from an exhausting disease, rising from bed for the first time the tone of the belly wall is lacking, the blood sinks down, the heart accelerates, the patient feels faint, or may actually faint. A faint is abolished by laying the man horizontal, or forcing him to bend and squeeze his belly against his thighs, or by strapping up his belly. Not only does the pulse quicken in the unfit, but the blood pressure falls when he stands up. There is a great difference between his systolic and diastolic pressures. His pulse, too, is greatly accelerated and may be made irregular by exercise. His vital capacity, also, as Martin Flack has shown in the case of unfit pilots, is greatly reduced, and he cannot hold his breath for long or blow hard against a column of mercury.

---

[1] An invention made independently and at the same time as that of Riva Rocci.

THE EFFECT OF EXERCISE ON CIRCULATION.

Those suffering from cardio-vascular debility, people convalescing from illness, or falling ill, those exhausted by war or flight-strain, alike fail in these tests. Flack has developed for flight cadets exercises designed to strengthen the expiratory power of the abdominal muscles, and made a most valuable application of the lessons learned from Fig. 3, taken from my second paper on Gravity and the Circulation, in which Barnard coöperated. It shows the brain enclosed in a rigid wall, the thoracic organs in a wall which enlarges by the action of the diaphragm in inspiration and so sucks in both air and blood into the thorax, and contracts in expiration, and so squeezes out of the thorax both air and blood. The belly organs are compressed by the descent of the diaphragm and enclosed in a muscular wall, which can be relaxed so as to admit food and drink and more blood, or contracted so as to expel the fæces or urine or drive out blood. The heart is shown enclosed in a pericardium,[1] which prevents its over-expansion, so that the contracting belly wall can squeeze blood through the right heart into the lungs, the entrance into and the escape of air out of the lungs being suitably controlled by the glottis. The diagram also shows the limbs encased in skin, so that every movement of the muscles and change of posture drives blood from capillaries and veins past the valves in the veins towards the heart. Clench the fist and one sees the blanching of the vessels on the back of the hand; lower the hand, they congest; raise it, they blanch. Hunter pointed out that dependance of a part and immobility produce œdema and delay healing by impeding the circulation, and that congestion produced by gravitation increases the pain felt in inflamed joints. The vessels in the body are arranged so that every muscular movement drives capillary and venous blood onwards. The peristalsis of the intestine not only moves to and fro, or sends onward, the chyme, but expels the blood out of the capillaries and the chyle out of the lacteals. The rhythmic contraction of the spleen converts this into a blood pump; similarly other organs are either squeezed by their own muscular coat, or squeezed as the liver is squeezed between the diaphragm and the muscles of the abdominal wall. In walking, still more in running, the deep breathing and movement of the muscles rhythmically express blood from the organs and venous reservoirs of the belly into the right heart, and through the right heart into the lungs, which are widely expanded in inspiration to receive it. The respiratory pump massages the belly organs and effectively aids the circulation. Vigorous exercise ventilates the lung, five, even ten times more, and sends the blood swirling in well-oxygenated streams through all parts, uses up the food that is eaten for the production of energy, and so ensures a clean bowel, good appetite, and well-nourished organs. The cooling power of the wind stimulates us to exercise in the open air to keep warm, and greatly enhances the value of the exercise.

Exercise in the open air and sea-bathing afford then the successful treatment for cardio-vascular debility. The sedentary life of the scholar, the sempstress, or the light hand worker in factories must be balanced by open-air exercise, facilites for which can only be secured by the rebuilding of tenement dwellings as garden cities, and the establishment of playing-fields and gardens. Be it noted that the gardens also afford the means of cultivating green vegetables and thus the securing of essential vitamines which the tenement dweller lacks.

THE RESILIENCE OF ARTERIES.

The arterial pressure in the femoral artery in cases of aortic regurgitation is much higher —e.g., 100 mm. Hg or so—than in the brachial artery with the patient lying horizontal. There is, too, a wide difference between systolic and diastolic pressures in these cases. I found that the pressure might be made higher in the femoral artery in healthy young men by making them run up and down stairs several times, so inducing a forcible heart beat; also that the difference in cases of aortic incompetence might be made less or even abolished by placing the buttocks in a bath of hot water. In healthy resting young men a difference might be detected between the right and left arm after their placing one in hot and the other in iced water. The iced upper arm might give a lower reading than the heated forearm.

If the wall of an artery is contracted and more rigid it conducts the crest of the pulse-wave much better than if the wall is soft and slack. In the latter case the crest of the pulse-wave spends its force in distending the wall of the artery.

On a model constructed by Russell Wells it was shown that the thinner a rubber tube the more it is stretched by the pulse-wave, the more is its resilience brought into action, and the less well is the crest of the systolic wave conducted, and the nearer together are the diastolic and systolic pressures at the peripheral end. A pump systolic pressure of 160 and diastolic 40 mm. Hg. gave, in a rubber tube 0·8 mm. thick, a sphygmogram showing great amplitude, sharp rise and fall, well-marked dicrotic waves; in a tube 0·2 mm. thick a slow rise, flat top, slow fall, slight dicrotic waves. In accordance with the contraction and rigidity of the arterial wall, the same heart beat delivers to the capillary-sized vessels hammer-like percussion waves, beating them open, or a more continuous but lower pressure of blood. In renal disease I think it is the cells, strangled by inflammatory processes, which call for the hammer stroke. Hence the high systolic pressure. The danger of cerebral hæmorrhage arises not from the high pressure, but from vascular degeneration set up by the abnormal metabolic conditions.

THE MEASUREMENT OF BLOOD PRESSURE.

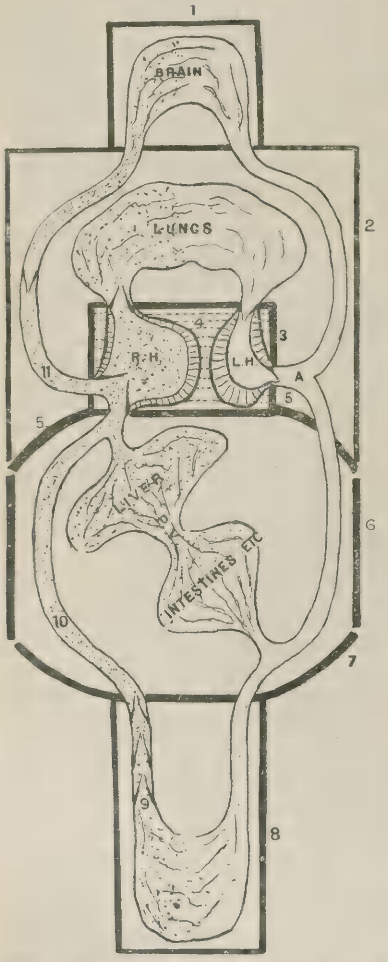
I now ask you to consider what happens when, in measuring blood pressure, the arm is compressed by the armlet. On raising the pressure the veins and capillaries in the part of the arm confined by the armlet are first compressed and the flow obstructed, the pressure rising in these vessels up to arterial pressure; the main artery is thus kept full and cannot be flattened until the pressure in the other vessels is over-topped. When the diastolic pressure is just over-topped the artery is flattened in diastole and swings into full round shape in systole, the pulse then giving its maximal excursion. The auditory method also gives an index, for when the pressure is raised above, and then allowed to fall just below what is required to flatten the artery in diastole, the noise (heard over the artery below the armlet) suddenly becomes quiet. Be it noted the maximal oscillation is just as true an indication of diastolic pressure as the auditory change of sound.

---

[1] The diagram shows shows how a pericardial effusion obstructs the filling of the heart.

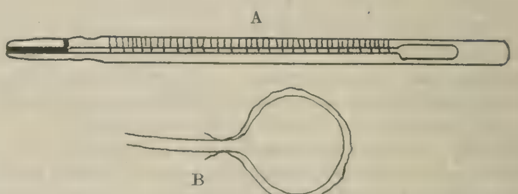
When the bag of my pocket sphygmomanometer (Fig. 4) is pressed upon the wrist over the radial it acts in the same way as the armlet, and the gauge gives the same readings of systolic pressure as the armlet sphygmomanometer. But in the case of an aberrant radial observed by James McQueen, as also in the dorsalis pedis (or temporal) artery, where it lies upon bone unsupported by tissues full of veins and capillaries, the bag gave a far lower systolic pressure. The pressure in the carotid artery in the dog measured on one side with the bag was the same as that on the other side measured directly by means of a cannula and a manometer. When, however, the carotid was exposed and placed on a flat piece of wood a far lower pressure of the bag sufficed to stop the pulse. The conclusion was reached that an artery, unsupported during compression by surrounding tissue vessels, is easily distorted from the round into a chink-like shape, and then the pulse-wave expends its force on dilating the artery above the chink, and does not pass through. This is why an arm with tissue vessels constricted by ice gives a lower reading than one with tissue vessels dilated by hot water.[2]

FIG. 3.



Schema of the circulation of the blood in man in the erect position. 1, Skull. 2, Thoracic wall. 3, Fibrous pericardium. 4, Pericardial effusion. 5, Diaphragm. 6, Oblique and transverse muscles. 7, Levator ani. 8, Skin and muscles of the legs. 9, Femoral vein and valves. 10, Inferior vena cava. 11, Superior vena cava. R.H., Right heart. L.H., Left heart. A., Aorta. P.V., Portal vein.

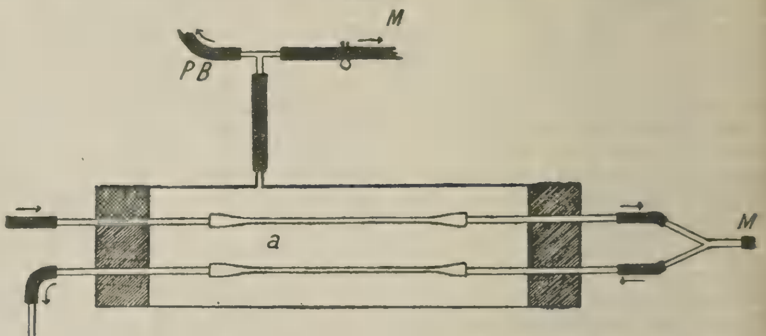
FIG. 4.



The author's pocket sphygmomanometer: (A) is the gauge, (B) the bag to press over the radial artery. (Made by Hicks, 8, Hatton Garden, E.C.)

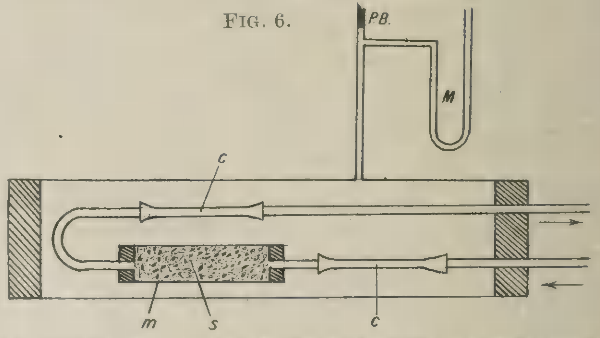
The facts may be largely demonstrated by a model. Fig. 5 shows a chamber containing two pieces of human carotid; water circulates through these with a pulsatile flow. Owing to frictional resistance there is a lower pressure in the distal piece. On compression this flattens first. When a single piece of artery is used the pressure required to distort its distal end and stop the pulse-wave passing is much lower than the pressure required to stop water trickling through.

FIG. 5.



Chamber containing two pieces of human carotid artery (*a*) through which water is made to circulate. Owing to friction the pressure is lower in the distal piece. M = manometer. PB = pressure bottle.

FIG. 6.



The same chamber as in Fig. 5, containing pieces of human carotid artery (*c*), with the addition of a thin rubber bag enclosed in muslin (*m*) and filled with chopped rubber sponge (*s*) to simulate the tissue capillaries.

Arranged as in Fig. 6, the flow is first through the artery, then through tissue capillaries, then through the vein. The tissue capillaries are formed of chopped rubber sponge enclosed in a thin rubber bag, and this in its turn enclosed in muslin to limit its expansion. The vein first flattens on compression and the tissue capillaries shrink (the pulsing artery expels fluid from these). The system then becomes more rigid, the pressure rising to arterial pressure all through it; next the artery flattens in diastole and finally in systole.

---

[2] Martin Flack and James McQueen coöperated in these researches.

MEASUREMENT OF CAPILLARY PRESSURE.

Roy and Graham Brown, observing under the microscope the capillary vessels in the mesentery, by means of a transparent bag squeezed them against a glass slide. It required very little pressure to begin to affect the flow. To stop it the pressure in the arterioles must be overcome. The capillaries do not alter in width when the circulation is stopped; they are not elastic tubes merely controlled by the arterial pressure. On the other hand, they may spontaneously alter in width under the influence of irritation or tissue activity.

The normal capillary pressure cannot be measured in man by the method of blanching the skin (Fig. 7): firstly, because the skin resists distortion; secondly, because the observation requires immobilisation of the part and the capillary-venous circulation is affected by every muscular movement and change of posture; thirdly, blanching signifies the shutting up of arterioles, not capillaries. I have endeavoured to measure the capillary pressure by inserting a hollow needle under the skin connected with a tube containing sterile water and an air-bubble index, and finding what pressure it takes to drive the index inwards. The pain produced by the entering droplet of water is also an index. Using this method one finds a very slight pressure suffices either for the arm or the leg, not only in the horizontal position but in the vertical posture. The capillaries do not share then in the hydrostatic difference of pressure shown by the arteries. If we hang down a hand and keep it immobile we soon cannot bear the ache produced by the capillaries congesting under the influence of gravity; naturally we shift the position of the part and empty the capillaries on into the veins. When an armlet is put round the upper arm and the pressure raised and kept just below systolic pressure the veins are obstructed, the capillaries fill, the hand swells, and the ache grows. If one then measures the pressure required to flatten the veins on the forearm, one finds the pressure has risen up to what it is in the armlet. (A proof that the armlet method reads the systolic pressure truly.) When the pressure in the main veins has risen considerably, it is still possible to express blood out of the capillaries and veins on the back of the hand by clenching the fist. It is generally assumed that if arterial and venous pressure are both raised capillary pressure must be raised, but we see by the action of the muscles and the valves in the veins it is possible to have a high pressure in both arteries and veins of a part, and no pressure in the capillaries until they once more fill.

FIG. 7.

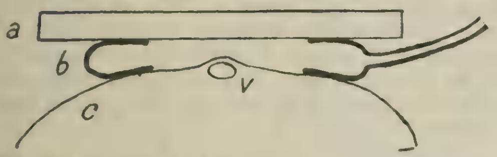


Diagram of measurement of normal venous and capillary pressure by the method of blanching the skin. *a*, Glass slide. *b*, Rubber bag with a hole punched through the middle. *c*, Arm. *v*, Vein.

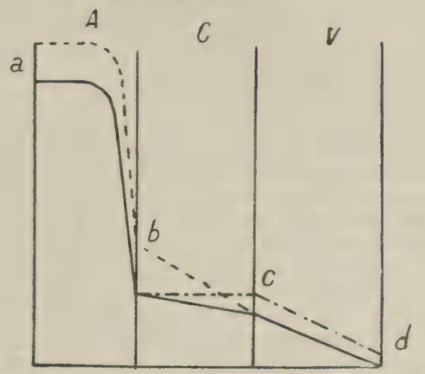
The vascular system is then not a continuous one like the models constructed to represent it. When the heart is stopped there is no uniform residual pressure; on the contrary, blood sinks into the lower parts, and upper parts empty and collapse. When the arterial pressure is raised by the constriction of arteries the rise is due wholly to increase of frictional resistance therein, none of it is due to reduction in the total capacity of the vascular system. We know that at any one time normally a vast number of the capillaries are empty. Krogh has recently brought fresh proof that this is so. Cold shrinks up the cutaneous capillaries, heat fills them; a vast difference pertains between the two conditions. The respiratory movements, the intestinal contractions, the movements of the skeletal muscles are all designed to squeeze the blood from the capillaries and keep a very low pressure within them.

FIG. 8.



Graph unsupported by evidence but given in text-books as showing the fall in blood pressure from the artery (*A*), through the capillary (*C*), to the vein (*V*), and the effect of raising arterial pressure (interrupted line) and venous pressure (dot and dash line).

The regulation of the circulation (1) by the cardiac nerves afferent and efferent (acceleratory and inhibitory); (2) by the vaso-motor nerves (constrictor and dilator); (3) by the compressive or expansive action of the voluntary, respiratory, and visceral muscles; (4) by change of posture and action of gravity is designed so as to keep steady the composition of the blood and fluid bathing the tissues. Thus during exercise the circulation is increased proportionately with the consumption of oxygen and production of carbon dioxide, and breathlessness in heart cases is the test of circulatory fitness and the capacity to take exercise.

The study of the immobile animal and of models leads away from the true conception of the mechanism. The circulation could not continue for a moment if all the blood-vessels, arteries, veins, and capillaries were freed from the support of the surrounding tissues and membranes which confine the tissues. These form a support to the vessels which is of no less importance than their own wall. The body requires to be kept hard in a lean and wiry state, with no excess of fat or tissue fluid, and no wind in the guts—a state in which the tissues, muscular and glandular, confined within their membranæ propriæ and capsules are maintained in turgescence, thus supporting the blood-vessels, whose coats have good tone, the whole confined in a firm cool skin.

THE CAPILLARY PRESSURE AND THE PATHOLOGY OF ŒDEMA.

Although there is no evidence of a higher pressure in the capillaries than in the tissue fluids, this is generally assumed, and it is supposed that filtration takes place from the capillaries—e.g., in the case of the renal glomeruli, formation of lymph, aqueous fluid, &c.—and that œdema is produced by increased capillary pressure and filtration. My view is that the tissue cells and fluid enclosed by capsules and skin exactly counterbalance any pressure there is in the capillaries, and that the cellular force of imbibition draws fluid out of the capillaries.

C. Bolton has shown that after obstructing the flow in the vena cava inferior, by narrowing it down by three-fifths, the venous pressure is only temporarily and slightly raised, and that œdema occurs after the venous pressure has returned to the normal level. Œdema is not due to filtration, but to obstruction of the flow of blood, leading to want of oxygen and metabolic changes in the cells, which result in increased imbibition. I found in a case of hydrocephalus that the fluid pressure equalled about 20 cm. of water. On raising the head from the pillow the pressure did not fall owing to gravity, but rose owing to my hands squeezing the head—a bag of fluid. It is not conceivable that the pial vessels could support any part of this pressure; the capillary venous pressure must have risen pari passu. On drawing off the fluid the pressure sank to atmospheric pressure and the soft wall of the skull by its weight sagged in. So it remained for hours, until, as the fluid was secreted, the pressure gradually returned. In a case of œdema of the leg I found the pressure equalled about 50 cm. of water, the patient was sitting up in bed; here, again, the pressure did not fall, but rose on lifting the leg up owing to squeezing of the leg by the hands. The capillary-venous pressure must have been the same as the fluid pressure.

We must bear in mind that the capillaries are evolved out of intracellular spaces, such as are found, for example, in a Turbellarian worm, in which a sort of circulation is kept up by movements of the animal's body. Pulsatile channels were next added, and finally hearts.

I have recently tried to get some measure of the normal capillary pressure by microscopic examination of the frog's web, mesentery, and tongue, after stopping the arterial flow (1) by ligature, (2) by excising the heart, (3) by cutting off the part—in this case the foot. The capillary circulation continues for several seconds, gradually becoming slower and finally stopping in most of the vessels. On exploring the field, however, there may be found one or more vessels—e.g., an arteriole with connecting capillaries and a venule—in which the flow continues for some minutes at a speed which is no less than the normal speed in the capillaries. The flow after a time may reverse. A slight movement of the limb may hasten the flow, reverse it, or may start a flow. Thus the replacing the frog's web under the microscope, 40 minutes after cutting off the leg, started a flow which lasted for some minutes. It seems clear to me, then, that the very slightest difference of pressure suffices to maintain the capillary flow. The fact that the flow reverses is against its being caused by any contraction of the larger arteries. So, too, is the fact that a slight movement of the amputated leg hastens the flow in the web of the foot. A search in the Royal College of Surgeons Library revealed that a French physiologist, Guillot, in 1823 made similar observations and found the heat of a candle accelerated the flow. I find a momentary exposure of the frog's web to the heat of a fire both starts and accelerates the flow. I would call to mind here the very remarkable flow in the so-called veins of the slime fungus or myxomycetes, which rhythmically reverses—first a rushing stream of granules towards the growing edge, then a stream away from the edge. The capillary flow seen in the excised foot of the frog is due, I think, either to evaporation or to blood sinking down into some dependent, or more flaccid, part.

The contraction and expansion of capillary-sized vessels has been demonstrated by many; recently by T. Lewis and his co-workers in the skin, and in the frog by Krogh. On irritation of a part local hyperæmia is brought about through the afferent nerve fibres—by "axon reflex." There is evidence that the metabolic state of tissue cells governs the flow, and I would urge that it is not the capillary wall but the swelling or shrinking of the tissue cells, and in particular of muscle, voluntary and involuntary, which controls the width of the capillaries.

The body may lose 7 lb. of water by sweating during hard exercise in hot weather. The tissues shrink and keep up the supply of water in the blood, which scarcely becomes more concentrated; the muscles must then increase their tone so that the skin and membranes confine the shrunken tissues and keep up the hardness of a fit person.

THE INFLUENCE OF MEMBRANÆ PROPRIÆ AND OTHER MEMBRANES ON THE CIRCULATION AND SECRETORY PRESSURE.

In the case of the salivary gland there is a strong membrana propria which confines the secreting cells of each alveolus, comparable to the sarcolemma of a muscle fibre or neurilemma of a nerve fibre. It limits the expansion of the alveolus, acting like the leather case of a football, the pericardium of the heart, or the connective tissue coat of a blood-vessel. Each lobule, each lobe, and the whole gland is surrounded with membranes limiting expansion. When the secretion is obstructed the alveoli swell, the lobules and lobes swell, and the whole gland swells until limited by the membranes, and the veins within the gland are compressed and diminished in volume, while the arteries dilate and the circulatory pressure is thus raised until arteries, capillaries, and veins approximate to a rigid system at arterial pressure with a fast rate of flow. As the membranæ propriæ, &c., limit the expansion of the alveoli, the veins are not shut up even when the duct is obstructed, and the secretory pressure rises much above the arterial pressure. Flack and I observed in one case that with 240 mm. Hg in the salivary duct and 130 mm. Hg in the carotid artery 27 drops flowed out of the salivary vein in 20 seconds. In the sweat glands the structure is similar to that in the salivary glands, and the same high secretory pressure may be produced.

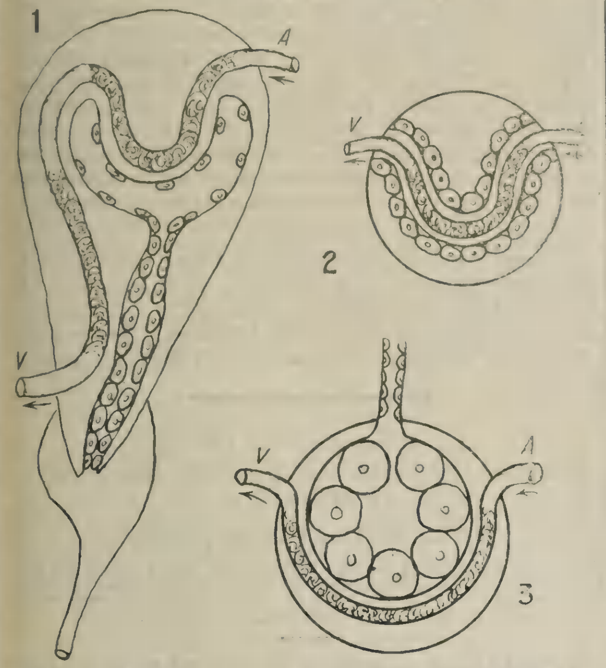
It is a fundamental principle in the construction of the body that the cells are enclosed by membranes which permit imbibition of fluid but check swelling, thus enabling them to do work and at the same time receive an ample supply of blood.

In the kidney there are membranæ propriæ enclosing the secreting cells of both renal capsules and tubules. The secretory pressure, however, does not rise up to the arterial pressure (133 mm. Hg carotid artery and 88 mm. Hg in the obstructed ureter—Starling). In the case of the kidney the bladder acts as a reservoir and the abdominal wall keeps off external pressure.

The structure of the kidney does not support the doctrine that fluid is filtered from the blood into the capsule of the glomeruli by the blood pressure. The glomerulus is a lobule of a gland secreting within a capsule. In worms the glomeruli hang in a blood space; filtration pressure cannot exist.

Obstruction of the ureter does not at first diminish, but increases the secretion of urine (Cushny). The whole gland then becomes tense and the blood flow rapid through a system of vessels approximating to a rigid system. Each pulse expels blood out of the veins and urine out of the collecting tubules.

FIG. 9.



Schematic figure of secreting cells, membrana propria, capillaries and capsule of: 1. Kidney. 2. Eye. 3. Salivary gland. A = artery. V = vein. From Flack and Hill's Text-book of Physiology (Arnold).

INTRA-OCULAR PRESSURE.

Now let us turn to some observations made on the eye, in which Flack coöperated. The pressure of the aqueous fluid was measured by a hollow needle thrust through the cornea connected with a tube containing an air-bubble index, and this in its turn with a pressure bottle and manometer. The pressure (20 mm. Hg or so) varies, as is well known, with the arterial pressure. That the pressure of the aqueous balances the capillary venous pressure in the iris is shown by the fact that on letting the fluid escape the iris bulges forward and may touch the cornea, and on compressing the abdomen the vessels of the iris burst; and blood comes into the anterior chamber. No such bulging or hæmorrhage can be brought about by squeezing the belly when the eye is intact.

One of the venæ vorticæ was opened and the venous outflow observed, while the pressure in the eyeball was raised by forcing normal saline into the aqueous chamber; the outflow of the venous blood did not cease until the pressure in the carotid artery was just overtopped, showing that the capillary venous pressure rises together and equally with the fluid pressure within the eyeball, just as within the cerebro-spinal cavity.

The contents of the eyeball are confined by the corneal membrane of Descemet and the glassy membrane of the choroid, supported by the cornea and sclera, and the intra-ocular pressure is ruled by the secretory action of the cells of the ciliary processes. If the cells secrete more aqueous there is less room for blood, the veins narrow, and the capillary-venous pressure rises. If the arterial pressure increase the capillary-venous pressure this increase is instantly transmitted to and balanced by the aqueous. The pulse causes a rhythmic expansion and shrinkage which keeps up the flow of blood and fluid.

Accommodation is established by a perfectly balanced transference of fluid from the front to the circumferential region of the lens; this transference, brought about by the ciliary muscle, causing the lens to become more convex.

The spaces of Fontana are covered by a layer of endothelium less than 1μ thick, and supported as this is by an equality of pressure, aqueous on one side, venous blood on the other, the normal absorption of aqueous takes place.[3] In the bloodless eye of the dead animal the spaces are converted into filtering structures on forcing fluid into the aqueous chamber. So, in the dead kidney, on driving water through the renal vessels it filters out through the dead collecting tubules, carrying with it degeneration products of the cells.

Abrading the skin, opening the eyeball or skull cavity in the living animal, removes in each case the balancing counter-pressure, and allows plasma to escape through the capillaries which are no longer supported. The cells and capillary wall, too, are damaged by exposure, and this enhances the outflow of fluid.

The Effect of Inflammation on the Circulation.

In acute glaucoma there are disordered metabolism and increased imbibition, while the pathways of absorption may be obstructed, for example, by dilatation of the iris. The increase of fluid lessens the volume of the veins and so raises intra-ocular tension. The surgeon's knife relieves glaucoma by allowing the outflow of fluid and inflow of blood, with its immunising properties, as in any other inflamed part.

The tissue cells in the skin are confined by frameworks of connective tissue which limit expansion and act as the membranæ propriæ of a gland. In states of inflammation the tissue cells swell, the arteries dilate and the pressure rises as the swollen tissues press upon and narrow the veins. The vessels approximate to a rigid system, hence the high tension and pulsatile-throb of the inflamed part. The flow from the veins witnessed in the old days of bleeding was two or three times greater in an inflamed arm. Finally stasis may be produced by exudation of plasma from the damaged capillaries. The surgeon's knife by cutting, the hot fomentation by softening, relieve tension and allow increased flow of blood and lymph to the part.

SOME REMARKS ON SHOCK.

I finally ask you to consider the condition of shock which may arise from intense nervous excitation; from absorption into the blood of toxic products probably of protein origin arising from traumatised tissues; from absorption of bacterial toxins and certain other poisons; from exposure to excessive heat; from hæmorrhage; from want of oxygen in the air breathed. When traumatic shock is well established no relief can be given by any measures taken to confine the capillaries—e.g., by bandaging the limbs. The blood is not only pooled within them, but fluid has transuded out.

---

[3] Ehrlich's study of aqueous secretion by the injection of fluorescein supports these views.

Crile upheld the view that traumatic shock is due to exhaustion of brain cells by intense sensory excitation, and that such could be prevented by local anæsthesia which blocked the sensory nerves. By suitable anastomoses of blood-vessels he cross-circulated two dogs, so that the blood of each intermingled; only the animal submitted to traumatism showed the characteristic changes in the brain cells. These were produced then not by products of traumatism in the blood but by sensory excitation. Severe traumatism of the brain itself did not produce the changes in the brain cells. No shock was produced in spinal animals by traumatism of the body below the point of section of the spinal cord. Similar changes in the brain cells were produced by fear, exhaustion through excessive activity, prevention of sleep, great loss of blood.

The sub-committee of the Medical Research Committee on Shock has brought forward evidence which favours the view that shock can be brought about by absorption of a substance or substances from killed and dying tissues; thus amputation of a limb may relieve shock by putting an end to such absorption. So, too, in the case of extensive burns of the skin, shock is regarded as resulting from absorption of products of protein decomposition. Local trauma—a burn or the wheal of a cane—causes capillary flushing and œdema provoked by damaged tissue products. Noteworthy is the observation by Dale that an etherised cat can be put into the condition of shock by an injection of histamine, but not the normal cat nor one anæsthetised with nitrous oxide and oxygen. On the one hand there is the cumulative effect of two poisons, on the other the protective effect of oxygen. In the state of shock produced by the injection of histamine in the etherised cat the whole of the potentially available capillary channels become patent, the blood percolates into the network of channels as a sponge. 50 to 60 per cent. of the plasma may pass out. A constriction of the arterioles holds up the arterial pressure, but the venæ cavæ are flaccid, half empty, the portal vein flat, the filling of the heart in diastole wanes. The liver and spleen are moderately pale, but the bowels show a diffuse dusky congestion.

Shock due to Increased Imbibition.

It seems to me that shock is due to metabolic products opening up all the capillaries and increasing imbibition in all the cells of the body at the same time; such products can be evoked in the cells by violent nervous stimulation, by want of oxygen or by toxic substances in the blood. Waller finds in people of nervous temperament that the electrical resistance of the current passing between the back and palm of the hand is lowered by emotional changes of consciousness. This is probably an index of the change brought about in the imbibition forces of the cell by nervous shock. The concentration of ions on the cellular membranes and imbibition of fluid by the cells are so changed in shock, that a generalised passage of fluid into extracellular spaces and flaccidity result, with pooling of the blood in dependent parts; the consequent failure of the circulation and oxygen supply intensifies the evil.

The quick breathing set up in shock by cerebral anæmia and want of oxygen washes CO_2 out of such of the blood as continues to circulate and increases the alkalinity of the tissues which receive it—e.g., heart and brain—for the alkali, which was bound to CO_2 in the blood, is taken up by the tissues when set free. There is, then, an alkalosis and not an acidosis in shock, and the injection of sodium bicarbonate is contra-indicated. (B. Moore.) The alkalosis lessens the sensitivity of the respiratory centre, and thus air containing 2 per cent. of CO_2 acts as a stimulant and secures better oxygenation of the blood.

Injection of Bayliss's gum saline is required to fill up the blood-vessels; the colloid gum retains the necessary salts within the blood-vessels. At the same time the patient requires oxygen inhalation, which can be given most suitably in an oxygen chamber. I have constructed, and am now testing, a light, collapsible, and transportable oxygen chamber, large enough to take nurse and patient, to be used in conjunction with liquid oxygen containers, and ventilated so that no re-circulation or purification of the air is required.

CONCLUSION.

In conclusion I ask you to consider not increased capillary pressure and filtration as the causes of œdema, but stagnation of flow with consequent oxygen want and increased imbibition. The result of such a shifting of ideas will, I believe, prove fruitful.

THE RESULTS OF
PROTECTIVE INOCULATION AGAINST INFLUENZA
IN THE ARMY AT HOME, 1918–19.

BY MAJOR-GENERAL SIR WILLIAM B. LEISHMAN,
K.C.M.G., C.B., K.H.P., M.B., F.R.C.P., F.R.S.,
DIRECTOR OF PATHOLOGY, WAR OFFICE.

THE LANCET published on Oct. 26th, 1918, the proceedings of a Conference of bacteriologists, summoned by the Director-General of the Army Medical Service to consider the advisability of employing in the army a preventive vaccine against influenza. This Conference, of which I had the honour to be chairman, agreed that such a vaccine might be expected to be of service, and made recommendations as to its constitution and use. The vaccine recommended was accordingly prepared at the Royal Army Medical College, and, in certain commands, used on a considerable scale.

In view of the opinion, widely expressed in both medical and lay journals, that we are threatened with another epidemic wave of influenza, it is felt that the results obtained in the army commands at home last winter with the vaccine in question should be made known, not only because it is proposed to advocate its employment again in the army, if we should be so unfortunate as to find ourselves in the presence of a serious recrudescence of the disease, but also because the modified vaccine now in army use has, I understand, been adopted by the Ministry of Health for employment in the civil community.

The Original Formula.

The vaccine formula recommended by the Conference mentioned above was as follows:—

B. influenzæ	60 millions	in 1 c.cm.
Streptococci	80 ,,	
Pneumococci	200 ,,	

Several strains and types of each organism were used, all comparatively freshly isolated from cases of the disease. Two doses were recommended, the first 0·5 c.cm., and the second, given after 10 days' interval, 1 c.cm. The statistical results recorded below apply solely to the vaccine prepared in accordance with the above formula.

As was naturally to be expected, in view of the divergent views held as to the bacteriology of the epidemic, the proposed constitution of the vaccine was subjected to a certain amount of criticism in subsequent issues of the medical press, and the points made in these communications, many of them most valuable and helpful, were duly noted. One of the principal criticisms was concerned with the dosage which had been agreed on as appropriate for the *B. influenzæ* moiety of the vaccine, it being urged that a considerably larger dose of this might be given with safety and with the prospect of an enhanced degree of immunity. In view of this, and also of the fact that, as the bacteriological experience of the epidemic extended, the ætiological rôle of Pfeiffer's bacillus came more and more into prominence, I consulted my colleagues of the original Conference afresh upon this point and found them all in agreement with an increased dose of Pfeiffer's bacillus, which I proposed should be raised from 60 millions to 400 millions in 1 c.cm., it being understood that the strains employed should not have been so cultivated or so recently derived from cases as to be unduly toxic in their action.

The Revised Formula.

The formula of the vaccine as thus revised, and as now employed in the army, is therefore :—

B. influenzæ	400 millions	in 1 c.cm.
Streptococci	80 ,,	
Pneumococci	200 ,,	

From the first it was desired that every attempt should be made to secure clear statistical evidence of the results of the inoculations with the vaccine, and the necessary instructions to this effect were circulated by the War Office, returns in accordance with a simple *pro forma* being called for at regular intervals. In theory such clear evidence should have been easy to collect through the workings of official machinery; in practice it has been very difficult. Only those familiar with the strain thrown on the medical personnel by the addition of a severe and widespread epidemic to the already sufficiently arduous labours of those days of urgent and wholesale demobilisation can appreciate the difficulties of collecting and recording, in accurate detail, the information required for the returns. In spite of these difficulties, which, unfortunately, vitiated some of the returns, a considerable number of inoculations were carried out, and the records were received and analysed at the War Office.

Although it is very far from my intention to make any claim that the figures presented below are conclusive and free from all or even, in some cases, from possibly large fallacies, they serve, I think, to show at least the general trend of the inoculation results, and they have encouraged the hope that, with the larger dose of Pfeiffer's organism now employed, the vaccine, should it be needed, may prove a powerful reinforcement to other measures of protection.

Explanation of the Table.

A few words are called for in explanation of the table. The individual returns are shown under the name of the unit or the principal station in or near which the soldiers in question were located. The period covered by each return is shown in a separate column. The "strength" is the "average strength" of the unit or station; no other method was possible in view of the fluctuations of the population. The "inoculated" include those inoculated before the period in question, as well as those done during it, while the "uninoculated" are arrived at by deducting the inoculated from the average strength. The number of cases, complications, and deaths are, of course, not averages, but actual figures derived from the hospital records. The recording of pulmonary complications is probably lacking in uniformity, since different medical officers may have taken different views as to the

TABLE OF RESULTS OF INFLUENZA INOCULATIONS IN THE HOME COMMANDS, 1918–19.

		Incidence of attack.	Incidence of pulmonary complications.	Deaths.
Inoculated	15,624	14·1	1·6	0·12
Non-inoculated ...	43,520	47·3	13·3	2·25

degree of bronchial or pulmonary involvement which should be taken as a complication.

The returns, all of which lie within the period between November, 1918, and April, 1919, comprise all those relating to this period which conformed to the following requirements:

1. That the vaccine used was that prepared at the Royal Army Medical College, according to the original formula.
2. That influenza should have been present in the unit during the period under review. In many stations where inoculation has been largely carried out there was a rapid cessation of the epidemic. Such returns would have swelled the total of the inoculations without throwing any light on their protective effects.
3. That only such returns are included as showed that at least one-tenth of the average strength had been inoculated, whether with one dose or two.

Information was asked for as to the interval occurring between inoculation and a subsequent attack of influenza, but the figures in response to this are too few to be worth analysing; it need only be said that they furnish little or no evidence of any increased susceptibility in the days immediately following inoculation, and that they throw no light of any value on the duration of the immunity conferred by the inoculations. The figures bearing on the latter point would, in any case, have been exposed to the fallacy that the epidemic was rapidly declining throughout the country, and that the inoculated population was drifting, with increasing rapidity, out of our control into civil life.

No bad effects were reported from the inoculations, and the reactions, in the overwhelming majority, were trivial or non-existent.

It will be noted from the table that nearly one-half of the inoculated had received only the first dose of the vaccine—i.e., one-third of the amount which we considered essential to effective protection. It is reasonable to assume that, had all received the full dosage, the protective results would have been still more evident. No statistical evidence bearing upon this point is, however, available.

The table had best be left to speak for itself, but it will, I think, be admitted that in general the results are encouraging and that they tend to confirm, and even strengthen, our original anticipations, which were, briefly, that at least a moderate degree of protection against infection might be expected, while more decidedly beneficial effects might be hoped for in a diminution of both the frequency and the gravity of the pulmonary complications.

Periodic returns have continued to be received since the period dealt with in the table, but these have been either negative altogether, as regards incidence of the disease, or show so few cases of influenza in either group as to be valueless from a statistical standpoint.

BRISTOL HOSPITAL SUNDAY FUND.—The Lord Mayor of Bristol has expressed his delight at the satisfactory progress of his Sunday Fund, which bids fair to show a substantial increase on last year's record total of over £5000. Collections to hand so far are bigger by 25 per cent. than the corresponding figures of last year. It is interesting to note that the movement towards coöperation between the hospitals receives such tangible support from the Bristol public, who, by means of this fund and the collections made by the various firms, show a certain approval of the principle of hospital union which has for some time past been under discussion in Bristol.

COMPLEMENT-FIXATION EXPERIMENTS IN INFLUENZA.

BY H. J. B. FRY, M.D. OXON.,
CAPTAIN, R.A.M.C. (T.);
AND
C. LUNDIE, M.D. GLASG.,
CAPTAIN, R.A.M.C. (T.C.)

IN the first part of a previous note[1] by one of us (H. J. B. F.) an organism isolated from cases of influenza was described and its morphological and cultural characters given. It was there stated that the serum of a patient from whose blood the organism had been isolated had shown definite complement-fixation with an antigen prepared from the organism. This result encouraged us to try a similar experiment with sera obtained from other cases of influenza, which had been investigated (H. J. B. F.) during the two previous waves of the epidemic. The sera from these cases were old at the time of this experiment. Although preserved in sealed glass capsules, and, as far as possible, kept on ice, some deterioration was to be expected. Owing to the decline of the influenza epidemic cases of recent influenza have been infrequent, but the sera from a few definite cases of a mild type have been examined together with other sera as controls. One of us (C. L.), as the pathologist in charge of the serological work of No. — General Hospital (Venereal), had very favourable opportunities for examining sera from syphilitic and other patients as controls. The complement-fixation experiments described below were carried out by him, and in order to render the test more rigid he was ignorant of the nature of the cases from which the sera were derived.

Experiments.

The experiments group themselves under the following headings:—

1. Old sera obtained from cases of influenza at the height of the epidemic 1918–19.
2. Fresh sera and cerebro-spinal fluids from recent cases of influenza.
3. Control sera (*a*) from normal individuals; (*b*) from syphilitic patients who have never had influenza; (*c*) from patients with no recent history of influenza; and (*d*) sera from patients suffering from other pyrexial diseases, typhoid fever, malaria, tuberculosis, &c.

The total number of influenza sera examined is 15, which includes: Influenza old sera, 5; influenza fresh sera, 8: and influenza cerebro-spinal fluids, 2.

Control Cases (32).

(*a*) Normal	Sera ... ... 3 Cerebro-spinal fluid 1 } with no history of influenza..	4
(*b*) Syphilitic sera with no history of influenza ...		10
(*c*) Syphilitic sera with histories of influenza not later than one year		6
(*d*) Sera from specific diseases	Typhoid	1
	Malaria	5
	Tuberculosis	3
(*e*) Sera from non-specific diseases		3

Serological Technique (*C.L.*).

(*a*) *Hæmolytic system.*—Sheeps' corpuscles were used in a 5 per cent. suspension after washing six times with saline. The corpuscular suspension was sensitised with 5 M.H.D. of rabbit anti-sheep serum (Burroughs and Wellcome) titre 1 in 2000–3000. Complement was guinea-pig's serum used fresh on the same day, and was titrated in the usual manner prior to each set of experiments.

---

[1] Fry: THE LANCET, 1919, ii., p. 51.

(*b*) *Sera.*—The test sera were inactivated at 55° C. for 10 minutes, and diluted 1 in 5 after inactivation immediately before use. It was found important that the sera should be kept sterile to prevent anomalous reactions.

(*c*) *Antigen* (*H. J. B. F.*).—The source of the antigen is the strain of the bacillus obtained by blood culture from the patient whose serum, as stated previously, gave a positive complement-fixation reaction. The 24-hour growth on an agar slope (+ 10) is emulsified in 2 c.cm. sterile normal saline. The emulsion is allowed to undergo extraction in the incubator at 37° C. for 12–18 hours. It is then centrifuged at high speed for 15 minutes. The supernatant opalescent fluid is pipetted off and stored in sterile glass capsules after heating to 60° C. for one hour.

(*d*) *The test.*—The antigen-serum-complement mixture is shaken and allowed to stand half an hour at room temperature, and then incubated for half an hour at 37° C. The fully sensitised red cells are added, and the whole re-incubated for half an hour at 37° C. The readings are then taken. In general the test was performed with an antigen control, a test serum control with 1 and 2 M.H.D. of complement, and the test sera were put up with unit volumes of complement containing 1, 2, 3, and 4 M.H.D. respectively.

Experimental Results : (*a*) *Antigen Titration.*

Four different antigens were originally prepared for testing their power of absorbing complement.

Antigen (1): Saline emulsion of a 24-hour agar growth heated to 60° C. for one hour.

Antigen (2): Centrifuged extract of a 24-hour agar growth unheated.

Antigen (3): Centrifuged extract of a 24-hour agar growth heated to 56° C. for half an hour.

Antigen (4): Centrifuged extract of a 24-hour agar growth heated to 60° C. for one hour.

Antigen (3) was the one used in the preliminary experiment already reported (loc. cit.). The titre of the complement-absorbing power of each antigen was determined on the same day as the tests on the influenza sera to be reported below. Each antigen was titrated in five dilutions (1 in 5, 1 in 7½, 1 in 10, 1 in 15, and 1 in 20 respectively), and each dilution was put up with two strengths of complement, 1 and 2 M.H.D. respectively. Each set of dilutions of antigen had one control using saline instead of antigen for each strength of complement.

Antigen 1.—All controls completely hæmolysed (1 and 2 M.H.D.). Antigen dilutions with 1 M.H.D. complement 1 in 20 dilution nearly hæmolysed. Antigen dilutions with 2 M.H.D. complement, 1 in 5 dilution, nearly hæmolysed. Antigen dilutions with 2 M.H.D. complement, 1 in 7½ dilution, completely hæmolysed. Antigen (1) was therefore used in a dilution of 1 in 7½.

Antigen 2.—All controls completely hæmolysed (1 and 2 M.H.D.). Antigen dilutions with 1 M.H.D., none hæmolysed. Antigen dilutions with 2 M.H.D., none completely hæmolysed. Antigen dilutions with 2 M.H.D., 1 in 20 dilution, nearly hæmolysed. Antigen (2) was therefore used in a dilution of 1 in 30.

Antigen 3.—All controls completely hæmolysed (1 and 2 M.H.D.). Antigen dilutions with 1 M.H.D., none completely hæmolysed. Antigen dilutions with 2 M.H.D., 1 in 20 dilution, completely hæmolysed. Antigen (3) was therefore used in a dilution of 1 in 20.

Antigen 4.—All controls completely hæmolysed (1 and 2 M.H.D.). Antigen dilutions with 1 M.H.D., 1 in 15 dilution, completely hæmolysed. Antigen dilutions with 2 M.H.D., 1 in 10 dilution, completely hæmolysed. Antigen (4) was therefore used in a dilution of 1 in 15.

(*b*) *Complement-Fixation Tests.*

Five old sera from influenza cases were then tested with each of the four antigens, the latter being put up in the dilutions stated above. Antigen (1) 1 in 7½, Antigen (2) 1 in 30, Antigen (3) 1 in 20, Antigen (4) 1 in 15. For each serum there were three serum controls and three reaction tubes, the former having 1, 2, and 3 M.H.D.'s of complement respectively, but containing saline instead of antigen. The reaction tubes had each one volume of the required dilution of antigen and one volume of complement dilution, the latter being so arranged as to give 1, 2, and 3 M.H.D.'s of complement respectively in the three reaction tubes. (Complement titration gave one volume of a dilution of 1 in 35 as containing 1 M.H.D.)

Results.

The results are shown in the Series I., in which—

+ means complete fixation of complement (no hæmolysis).

− means no fixation of complement (complete hæmolysis).

± means more than half of complement fixed (less than half hæmolysis).

∓ means less than half of complement fixed (more than half hæmolysis).

tr. means almost complete hæmolysis.

Remarks on Cases in Above Table.

1. Original case from which organism was derived in blood culture. Temp. 104° at b.c. Recovery. Serum taken in convalescence.

2. Temp. 102°–104°. Recovery. Blood taken during pyrexia.

3. Blood taken during convalescence 10 days after fall of temperature to normal.

4. Severe case. Both lungs involved. Blood taken during pyrexia.

5. Severe case, Temp. 104°. Blood taken 5 days after fall of temperature to normal.

The age of the sera in Series I. may account for a certain amount of fixation of complement in the serum control tubes. In each case, however, there is a greater degree of fixation of complement in the reaction tubes than in those of the controls, in some cases considerably greater. All the sera were derived from severe typical cases of influenza during the second wave of the epidemic, November, 1918, to January, 1919. Antigen 4 proved to be the most satisfactory antigen in the above series, and was at the same time the least anticomplementary.

The above results suggested further experiments with sera from more recent cases of influenza using Antigen 4, which was the one employed in all subsequent experiments. The results are given in the table (Series II.).

SERIES II.—*Influenza, Fresh Sera, 8 Cases; Cerebro-spinal Fluid, 2 Cases; Total, 10 Cases.*

* See notes below.

Remarks on Cases in Above Table.

1. See notes below. Agglutination 1/50 with bacillary emulsion.
2. See notes below.
3. Rejected. Serum contaminated.
4. See notes below.
6. Doubtful case of influenza clinically.
7. Influenza in February, 1919, under observation for syphilis.
8. Influenza in July, 1918, under observation for syphilis.

Clinical Notes. (*H. J. B. F.*)

The results in certain of the experiments in Series II. are so definite that short clinical notes of the cases from which the sera were obtained are given below.

1. Cpl. J., age 29, admitted 27/6/19. History: Sudden onset with headache, fever, and weakness 25/6/19. No marked pains in body, no cough. No previous attacks of influenza. Temperature on admission 103° F. Tongue furred, face flushed, slight diminutions of breath sounds at both bases, together with fine crackling crepitations; a few rhonchi at right apex. Blood culture 27/6/19 proved sterile. 2/7/19: Temperature fell by crisis below normal, followed by rise to 102° at night; fine rhonchi, and crepitations at both bases behind, with diminished vocal fremitus. 9/7/19: Rise of temperature after being normal three days. Small patch of bronchial breathing at left base, with increased vocal resonance and crackling crepitations. 13/7/19: Percussion note impaired at both bases behind. Breath sounds absent. Vocal resonance diminished. Profuse blood-stained expectoration, continuing 3–4 days. 17/7/19: Temperature normal, lung signs diminishing, and condition good.

2. Pte. S., age 28, admitted 4/7/19. Sudden onset 2/7/19, with pain in chest and cough and blood-stained sputum. Face dusky and cyanosed. Diminution of breath sounds at both bases. No adventitious sounds. Viscid, mucinous, blood-stained expectoration. Pulse regular, but feeble. No previous attacks of influenza. 5/7/19: Blood culture and cerebro-spinal fluid both proved sterile. 6/7/19: Temperature fell from 105° to normal. No physical signs in lungs. Pulse much improved in volume and tension. Expectoration remained blood-stained for a time. 9/7/19: Rapid general improvement. No further physical signs in heart or lungs.

3. Drvr. P., age 28, admitted 5/7/19. Sudden onset 5/7/19, with fever, headache, and pains in body. T. 102·6°. Influenza two years previously. Dry cough, slight pain in right side of chest. Blood culture 6/7/19 proved sterile. 7/7/19: Temperature down to 99°. No physical signs.

4. Pte. K., age 19, admitted 23/7/19. Sudden onset 21/7/19 with pain in body, headache, and weakness in legs. Slight cough and expectoration. No previous attacks of influenza. Face dusky, eyes injected, herpes on upper lip; heart, first sound rather short and of poor quality. No physical signs in lungs. T. 101°–103·8°. 24/7/19: Blood culture proved sterile. 27/7/19: Temperature gradually falling; slight epistaxis; slight diminution of breath sounds at right base and diminished vocal fremitus. 29/7/19: Again slight epistaxis. 1/8/19: Temperature normal.

4. Pte. H., age 24, admitted 21/7/19. Malaise from 16/7/19. Worse on 20/7/19 with headache and pains in chest and weakness. Not much cough. T. 101°–102°. No physical signs. No previous history of influenza. 23/7/19: Blood culture proved sterile. 24/7/19: Temperature fell by crisis and remained normal.

6. L/Cpl. L., age 28, admitted 7/8/19. Onset with headache and pains in right side of chest. T. 103°. No previous attack of influenza. 9/8/19: Respiration difficult; pallid, sweating. Heart not enlarged; first sound rather weak, pulse fairly regular and of good volume. Percussion note resonant all over chest, vocal fremitus diminished at the bases. No adventitious sounds. Breath sounds vesicular. Sputum muco-purulent, viscid, and, slightly blood-stained. 10/8/19: A few fine crackling crepitations at left base and fine rhonchi. 12/8/19: Pale and slightly cyanosed, but better. Fine rhonchi and crepitations all over both sides of chest. Bronchial breathing over small patch below angle of right scapula. Heart slightly dilated. 12/8/19: Expectoration profuse and blood-stained. Temperature normal. 14/8/19: Much improved, very few rhonchi in lungs, a few fine crepitations in both lungs, slight diminution of vocal resonance at right base, no dullness on percussion. 16/8/19: Lungs clear of adventitious sounds. Condition good.

Cerebro-spinal Fluids.

B. Coolie X.—Onset with symptoms of influenza, T. 103° F., and signs of broncho-pneumonia in both lungs, especially left. Developed cerebral symptoms with marked rigidity of muscles of neck, with a positive Kernig's sign, and extensor plantar response. Lumbar puncture 20 c.cm. fluid removed under fair pressure, turbid, and slightly blood-stained. Films from fluid showed a few polymorphonuclears and lymphocytes. No intra- or extra-cellular cocci seen, but a few Gram-negative bacilli. Culture was obtained on Matthew's medium, but the organism was subsequently grown in pure culture on agar, and was used as a control antigen (see below). Patient died, but no post-mortem examination was permitted.

Control Experiments.

Controls were carried out on sera from normal individuals who were free from any history of influenza, on sera from patients under investigation for syphilis, and on sera from patients suffering from ascertained diseases. Two serum controls were put up with saline instead of antigen containing 1 and 2 M.H.D. of complement respectively, and four reaction tubes containing 1, 2, 3, and 4 M.H.D. complement.

1. *Normal sera.*—Three sera, with negative serum controls, from individuals who had never had influenza, were all completely negative (1, 2, 3, and 4 M.H.D.). Cerebro-spinal fluids: One normal cerebro-spinal fluid similarly gave a negative reaction (1, 2, 3, and 4 M.H.D.).

2. *Syphilitic sera.*—(*a*) With history of influenza: Of sera from 16 cases, 6 had influenza at varying dates from August, 1917, to June, 1918, of these 1 only (influenza, June, 1918) gave a partial reaction (∓ – – –). The remainder were negative in all four dilutions. (*b*) With no history of influenza: The remaining 10 sera were from syphilitic cases free from any history of influenza. The reactions were negative in all four dilutions.

3. *Sera from specific diseases.*—(*a*) Typhoid: In one case of typhoid (*B. typhosus* recovered by blood culture and from fæces) the serum taken during convalescence was negative in all four dilutions. (*b*) Malaria: Of five cases of malaria (parasites in blood films) three had a history of influenza. One with a history of influenza in July, 1916, gave an incomplete negative reaction (± ± – –), the second with a history of influenza in September, 1918, gave a doubtful reaction (± ? – –). The third, with a history of two attacks in 1912 and 1916, gave a strong positive reaction (+ + + +). The remaining two cases (Austrian prisoners) stated that they had no history of influenza. The sera gave incomplete negative reactions (+ ∓ – –) and (+ ∓ ∓ –). The blood specimens were taken a few hours after the rigor, during pyrexia. (*c*) Tuberculosis: Three cases with tubercle bacilli in sputum were investigated. One was complicated by an acute gonorrhœal infection with fever and epididymitis. The reaction was completely negative in this case, and there was no history of influenza. Of the sera from the two remaining cases one with no influenzal history gave a complete negative reaction, the other gave a positive reaction (+ + + –), but had a history of a severe fever of unknown nature in October, 1918, at the time of the influenza epidemic.

Sera from pyrexias of unknown origin (*3*).—One case of a simple catarrhal jaundice with pyrexia (blood culture sterile) gave a completely negative reaction, and the patient had never had an attack of influenza. Two other cases of pyrexia of undetermined origin, with sterile blood cultures and agglutinations negative for typhoid-paratyphoid group, gave negative reactions. There was no recent history of influenza in these cases.

Control experiments with an indifferent antigen.—An endeavour was made to control the specificity of the antigen described above by means of an antigen prepared in exactly the same manner from a lactose-fermenting coliform organism found as a contamination in the cerebro-spinal fluid of a case of influenza (v.S.). Eight sera were tested against this organism as antigen. Three of these sera from cases of influenza had given a quadruple positive reaction with the "influenza antigen;" but gave a quadruple negative with the coliform organism as antigen. Five sera from cases of influenza which had given partial reactions with the "influenza antigen" gave quadruple negatives with the antigen from the coliform organism. The coliform organism did not, therefore, exhibit any of the antigenic properties shown by the organism under investigation.

Discussion of Results.

Owing to the decline in the incidence and virulence of the influenza epidemic and to difficulties connected with demobilisation, the results given above are somewhat scanty and incomplete, but are recorded under present circumstances in the hope that they may serve as a basis for criticism and further investigation. It seems legitimate to assert that the antigen prepared from the organism investigated shows definite fixation of complement with sera from cases of influenza. The results obtained in the case of the old sera are open to criticism owing to the fixation of a certain amount of complement by the sera themselves though the difference in the amount of complement fixed by the serum controls and the test sera is well marked in all the cases with Antigen 4. The old sera were all derived from severe cases, but the recent cases of influenza investigated have all been of a relatively mild type, which may perhaps account for some anomalous reactions. In Case 4 of Series II. a negative result was obtained with the serum in the third week after onset, after a weak positive reaction had been obtained with the serum in the first week. The serum obtained in the fourth week, however, gave again a fairly strong positive reaction. In Case 5 of the second series the negative results with serum obtained in the third and fourth weeks after a strong positive reaction with the serum obtained in the first week after onset may perhaps be explained by the rapid disappearance of the immune bodies after a short mild attack. This would accord with the clinical experience of second attacks of influenza at short intervals during the recent epidemic. In most cases the immune bodies as determined by the complement-fixation reaction do not appear to persist in the blood for a longer period than about one year (Case 8 and controls). Two cases, however, a malaria control and a tuberculosis control, gave strong positive reactions after three years' interval if the histories are reliable. It may be objected that mild cases of influenza are difficult to differentiate as clinical entities. The recent cases examined appeared to be genuine cases of influenza, and clinically to resemble the early cases seen in the first wave of the epidemic in the summer of 1918. It may be mentioned that two cases, which were at first considered to be cases of influenza but proved to be otherwise, gave completely negative reactions. No. 6 in Series II., though included amongst the cases of influenza, was not a typical one and the complement fixation reactions were negative.

It is significant that there was no case free from any history of influenza which gave a positive reaction, except two cases of malaria with doubtful histories, while no case with a definite recent history of influenza gave a completely negative reaction. In Cases 1 and 2 of Series II. a negative reaction with serum obtained shortly after the onset of the disease was followed by a strong positive reaction with sera obtained in the third and second weeks respectively, indicating the production during the course of the disease of antibodies in response to an infective agent, which was similar in nature to the original organism isolated during the third wave of the epidemic in February, 1919. It should also be noticed that in Case 1, Series II., an agglutination reaction to the same organism was obtained with serum at different periods of the disease in dilutions of 1/50 to 1/125 (Dreyer's technique). These results therefore bring the recent infections into relation with those of the previous waves of the epidemic by a common antigenic factor.

Summary.

1. An antigen prepared from an organism isolated in the third wave of the epidemic shows fixation of complement with sera derived from cases of influenza, both recent and those occurring in the previous waves of the epidemic.

2. This complement-fixation is absent in the case of sera from normal individuals who have never had influenza.

3. It is absent in the case of sera from individuals who are suffering from other specific diseases and are free from any recent history of influenza.

4. An antigen prepared from another organism shows no fixation of complement with sera from cases of influenza.

THE PERIODICITY OF INFLUENZA.

BY C. O. STALLYBRASS, M.D. LOND., D.P.H.,
ASSISTANT MEDICAL OFFICER OF HEALTH, CITY OF LIVERPOOL.

Dr. John Brownlee, statistician to the Medical Research Committee, in an article published in THE LANCET recently,[1] gave evidence that influenza has a periodicity of 33 weeks—i.e., that epidemic waves recur at intervals averaging 33 weeks, or multiples of 33 weeks. He further pointed out that from July 13th to March 1st (the maxima of the summer wave of 1918 and of the spring wave of 1919) is 33 weeks, but that the wave having its crest in this country on Nov. 2nd, 1918, does not fall into the sequence, leaving one to infer that there were two strains of the influenzal virus in operation. The brevity of his note concealed the immense amount of work which the investigation must have involved.

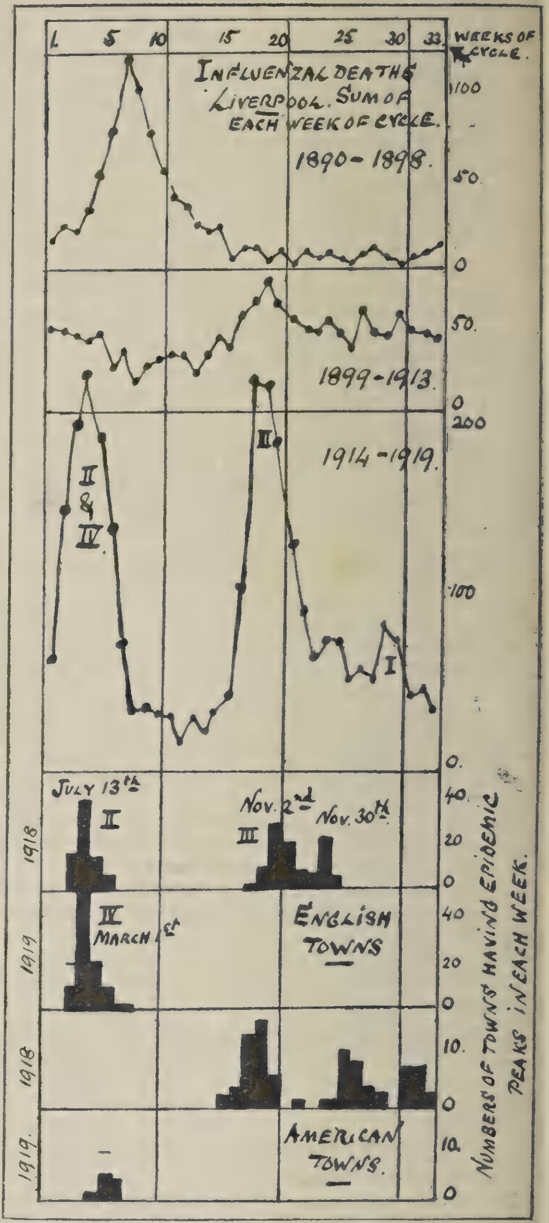
Brownlee stated that he had only been able to obtain weekly figures of deaths from influenza, pneumonia, and bronchitis for the City of London; I am able to supplement his investigation by the weekly deaths occurring in Liverpool during the period 1890–1919 that were ascribed to influenza and to all respiratory diseases. Prior to 1890 there were no deaths attributed to influenza for a number of years.

The following table is based on his periodicity of 33 weeks; starting with the first week in January, 1890, which I term the first week of the cycle, the weekly deaths are arranged in rows of 33, the resulting 33 columns being totalled for the two subperiods 1890–1913, 1914–1919; this division was adopted because from 1914 onwards there was a progressive increase in the annual number of influenzal deaths, 1917 excepted, which totalled 78, 100, 171, 55, and 1388 in successive years. The columns of the table show the weeks of the cycle of 33 weeks on which maxima occur, and the figures in brackets are the totals for those weeks :—

—	II.-IV.	III.	I.
Liverpool: Deaths from influenza—			
1890–1913	7th week (152).	19th week (81).	27th week (69).
1914–1919	4th week (221).	18th & 19th weeks (218 & 216).	29th week (80).
Liverpool: Deaths from all respiratory diseases—			
1890–1913	7th week (2729).	19th week (2565).	27th week (2484).
1914–1919	3rd week (706).	19th week (711).	—
96 English towns: Corresponding weeks of maxima 1918–19[2]...	4th week (July13th and March 1st).	20th week (Nov. 2nd).	—
American cities: Corresponding weeks of maxima 1918–19[3]...	6th week (March 15th).	19th week (Oct. 26th).	31st & 32nd weeks (Jan. 18th and 25th).

I have added for the purpose of comparison the weeks corresponding to those of the cycle in which the various waves reached their crests in the greatest number of towns in England and Wales and in the United States.

Closely corresponding with Brownlee's observations on London by far the most definite periodicity is shown during the years 1890–1899, during which period there is one well-marked maximum at the seventh week of the cycle. During the period 1899–1913 a new maximum in the nineteenth week of the cycle comes into play and continues to recur until the culminating point is reached in the week ending Oct. 26th, 1918, a week earlier than in most English towns (Wave III.); a further 66 weeks carries one forward to the first week in February of this year, as Brownlee pointed out, and the outbreaks that are being reported in Japan, Paris, Chicago, New York, &c., would show that this strain has punctually reappeared. These points are illustrated in the diagram.



There is also evidence in the table of a small maximum at the twenty-seventh week of the cycle in the earlier subperiod, and at the twenty-ninth week in the later subperiod; slight movements of the maxima forwards or backwards in the cycle over a number of years may, perhaps, indicate a periodicity slightly greater or less than 33 weeks. The twenty-ninth week of the cycle fell on the weeks ending May 18th, 1918, and Jan. 10th, 1919. An examination of the figures in Dr. Hope's annual report for Liverpool for 1918[4] shows that there was a definite wave of influenza reaching its crest on May 18th (Wave I.), and there is also a definite rise in the deaths from influenza, respiratory diseases, and from all causes, making a small peak in the week ending Jan. 3rd, 1919, but it is hidden by the enormous waves of October and March, so that it only appears as an irregularity in the curve; but it was noted at the time that influenza had not declined in Liverpool during January in the way that it had in practically all other English towns.[5] These two waves do not appear to have played a large part in this country, but the outbreaks in the Grand Fleet in May, 1918,[6] and also in Spain, Glasgow, &c., may, perhaps, be attributed to it. In the U.S.A. in January, 1919, it would appear to have played a much larger part. In a large number of American cities two waves were experienced, the first being the October wave; the crest of the second wave sometimes fell in March, as did one of the crests in this country, but in a number of instances—e.g., Cambridge, Washington, San Francisco, New Orleans, &c.—it fell in January, or to be exact, in the thirty-first and thirty-second weeks of the cycle. The close relationship of Liverpool and Glasgow with the United States through the incoming stream of American troops may perhaps account for the presence of this May wave in these two towns, and not in the rest of England.

The third maximum in the fourth week of the cycle is represented during the late outbreak by the waves culminating in Liverpool, and also the greater number of English towns on the weeks ending July 13th (Wave II.) and March 1st (Wave IV.). This is a 33 weeks interval. This wave recurred at an interval of 32–34 weeks in a large number of English towns.

The annual report of the Medical Department of the Local Government Board for 1918–19 gives a valuable table (Table III.) showing the exact week in which the three main waves, summer, autumn, and spring, reached their crests or epidemic peaks in each town; this table may be epitomised so as to show the numbers of towns having their epidemic peak in successive weeks as follows:—

(II.) *Summer Epidemic* (*68 Towns*).

Week ending—		Week ending—	
(1) July 6th	15	(3) July 20th	12
(2) ,, 13th	36	(4) ,, 27th	5

(III.) *Autumn Epidemic* (*96 Towns*).

Week ending—		Week ending—	
(0) Oct. 19th	2	(4) Nov. 16th	7
(1) ,, 26th	9	(5) ,, 23rd	6
(2) Nov. 2nd	27	(6) ,, 30th	22
(3) ,, 9th	19	(7) Dec. 7th	4

(IV.) *Spring Epidemic* (*95 Towns*).

Week ending—		Week ending—	
(1) Feb. 22nd	12	(4) March 15th	10
(2) March 1st	50	(5) ,, 22nd	1
(3) ,, 8th	21	(6) ,, 29th	1

Of these towns only 65 are shown as experiencing all three waves, and the remainder, including both towns having their maxima in the week ending Oct. 19th, may be excluded for purposes of comparison. On this basis the largest number of towns fall in week (2) in each of the three epidemics, but whereas the summer and spring epidemics are practically confined to four weeks for their maxima, the autumn epidemic is spread over seven weeks. Now, on the basis of a periodicity of 33 weeks it might be expected that a town having the crest of its epidemic in any week of the summer series should have its spring recurrence in the same week or, at any rate, within a week on either side, but that there need be no such connexion between the time of the crest of the autumn wave and the times of the crests of the summer and spring waves respectively. This is suggested by the frequency curve—i.e., the distribution of the numbers of the towns as given above, and is borne out by a closer analysis. Thus of 65 towns which experienced all three waves 47 (72 per cent.) had their maxima in the summer and spring epidemics within an interval of 32–34 weeks; but comparing the week in which any given town had its epidemic peak in the summer and autumn, and autumn and spring epidemics only 27 (41 per cent.) and 31 (47 per cent.) respectively fell within the limit of a week on either side. The time relationships of the maxima in summer and spring were much closer to each other than they were to the autumn maxima.

If it should prove correct that there were three strains of the influenzal virus, each with a periodicity of about 33 weeks, and that simultaneously all three strains became enhanced in both virulence and infectivity, then we are faced with a phenomenon without an exact parallel, although the behaviour of the meningococcal viruses during the war presents some points of similarity. So far the weight of evidence leans to such an exaltation of a widespread endemic strain or strains rather than to dissemination from any particular focus in the world. In any case doubtless a good deal of spread of infection took place.

There is some evidence pointing to the existence in this country not only of a minor cycle of 33 weeks but also of a major cycle round about ten years maxima, although of varying intensity, having been reached in the years 1789–90, 1802–03, 1830–32, 1840–41, 1848–49 and 1851, 1854, 1869–70, 1879, 1890–91, 1898, and 1918–19. With the exception of 1854, all these dates are about the end of a decennium.

AN EFFICIENT AND ECONOMICAL PYLON.

BY W. MONTGOMERY JOHNSTON,
L.R.C.P. & S. EDIN., L.R.F.P.S. GLASG.,
MEDICAL OFFICER IN CHARGE OF LONGFORD HALL LIMBLESS HOSPITAL, STRETFORD, AND BASFORD HOUSE LIMBLESS HOSPITAL, STRETFORD, MANCHESTER.

THE important features of this pylon are: (1) A bucket moulded to fit the stump, and supported by a fibre cone with a satisfactory rim at the top; (2) simplicity of design; (3) light weight and low cost of production. All these points have been kept in view during the experimental stages of development.

Details of Construction.

I will endeavour to illustrate the most important details in the manufacture of a thigh pylon. (Fig. 1.)

The patient stands on an elevated platform 1 foot high, at the side of which is an arrangement for holding his crutch. A fine gauze bandage, 6 yards long by 6 inches wide, is unfolded and dusted with plaster-of-Paris (preferably dental plaster). It is then rolled up loosely, and, after being soaked in water for two or three minutes, is squeezed and lightly rolled on the greased stump, so as to cover all the fitting surface required for the formation of the bucket, being careful in the process to keep well below the perineum (about 2 inches) and 1 inch below the ischial tuberosity. The bandage is carried higher on the outer side of the stump, so that when the bucket is completed the outer side of the rim at the top is generally 2 inches higher than the inner. (Fig. 2.) While applying the bandage all prominent ridges or folds on the surface are flattened out by hand.

The bucket, when formed, requires about five minutes to set hard. While it is hardening in position the measurement of the length of pylon required is taken. Before proceeding to do this it is essential to see that the anterior superior spines of the ilium are level, otherwise subsequent alterations will have to be made. With the patient standing, the distance is measured from the outer side of the top of the bucket to the platform, if possible in the direction of the heel in the normal subject standing to attention. This measurement is noted for further reference when making the cone.

By gentle manipulation, after hardening, the bucket will slide off the stump. It is then put aside until dry, when it is strengthened by gauze bandage incorporated with a thin solution of glue in water, strength about 1 in 4. (Fig. 3.) This is accomplished by painting glue solution on the bucket while the bandage is applied. It is again put aside to dry, and when sufficiently dry a leather lining, first cut from a paper pattern, is fixed on the inside by rye flour paste or thin glue solution, the leather being sufficiently large to turn over each end. It may require several small incisions above and below to simplify turning over. While drying, contraction of the lining can be prevented by filling the bucket with dry sand.

After the lining has dried sufficiently a rubber collar is fixed to the upper end of the bucket. (Fig. 4.) The rubber collar, or top, is made in the following manner: A piece of sheet rubber ⅛ inch thick, from 4 to 5 inches wide, and of sufficient length to surround the outside of the upper part of the bucket, is laid flat on a table and secured by pins or fine nails. After being well rubbed with glass-paper it is coated with good rubber tyre solution and allowed to dry. A rope is made from felt ¼ inch thick and 1½ inches wide, and of the same length as the rubber. The felt is rolled, and by a continuous stitch through the centre is formed into a circular band. (Fig. 5.) This is placed longitudinally in the centre line of the rubber, which has been re-solutioned. (Fig. 6.)

The rubber is then folded over the cord, forming a collar which appears on section as illustration. (Fig. 7.) The flat adherent ends of the rubber surrounding the cord are held in position until dry by metal rods and clamps. The collar thus formed is a flat rubber band with a round top; the flat part, preferably 1½ inches deep, is fixed by four or five bifurcated rivets to the outside of the top of the bucket, so that the round part clears the top. The ends of the collar are made to meet on the outer side and are kept in direct contact without a gap by covering with a small strip of leather 1½ inches wide. The bucket is now complete. (Fig. 4.)

The Fibre Cone.

This is made from compressed cane fibre 1/16 inch thick. One end supports the bucket and the other end is fixed to a wooden block. Besides fitting the bucket, the cone is made to support the round part of the rubber collar at the top.

Cutting the fibre for the cone.—Before this is done an outline from measurements is drawn on the fibre. The length of pylon required having already been noted on the patient's first attendance, deduct from this 2 inches for the wooden block, ½ inch for the rubber heel pad, and 1 inch for the rubber top, and in practice the result gives the measurement most suitable for the centre line of the cone. This gives a longer cone than is necessary for the finished pylon, but which when trimmed above and below to fit the bucket and wooden block will be found satisfactory in length.

Now measure the outside of the rubber collar where it is riveted to the bucket, and the outside of the bucket a few inches lower down, also the circumference of the wood block, adding to each measurement an inch for overlap. The length of fibre required (previously noted) is marked on the fibre by a straight line. This line meets at right angles at one end, the centre of measurement for the top of the bucket. Three or four inches lower down it meets at right angles the centre of the lower line of measurement of the bucket, and at the opposite end it meets at right angles the centre of the circumference of the wooden block. The ends of the top, lower, and bottom lines are connected by a straight line. This marks out the fibre required for making the cone.

Holes are punched out at equal distances from the sides of the fibre and at equal distances apart. (Fig. 8.) A space of 2 inches is allowed between each hole, which is punched ½ inch from the edge throughout the entire length. Copper rivets are inserted in the holes on one side of the fibre. The other side is folded over and fastened on the rivets, washers are put on, and the cone riveted up.

Fixing the Bucket in the Cone.

The bucket, as previously stated, being higher on the outer side, will not fit the top of the cone as at present formed without alteration. This is made by cutting the fibre in line with the circumference of the bucket below the round margin of the collar which it supports. The bucket being pressed firmly home, it is secured to the fibre by inserting three or four copper rivets about 1 inch from the top.

Fitting the Cone to Wooden Block.

Two sizes of blocks are used, each one about 5 inches long and with a double taper. (Fig. 9.) The larger size has a diameter at the top of 3½ inches and a tapered diameter of 3 inches. The medium size has a top diameter of 3 inches and a tapered diameter of 2½ inches. This is the size most commonly used. The end of the fibre part of the cone forms a collar round the upper tapered part of the block, to which it is fixed by screws with washers. A rubber pad, preferably made from an old motor-car tyre cover, is fixed on the end of the block by screws. This pad is found most useful and economical.

In the case of a short thigh stump a pelvic band is fixed to the outer side of the cone above. It consists of a vertical hinged rod about 9 or 10 inches long, ½ inch wide, and ⅛ inch thick. The rod has holes drilled for riveting to the outer side of the cone above. It is fixed at right angles to a flat curved metal band about 1 inch deep and ⅛ inch thick. This band is pliable. It approaches the middle line behind, curving round one side towards the middle line in front.

The joint of the vertical rod is placed as near the hip-joint as possible, the flat curved band lying in the hollow between the crest of the ilium and great trochanter. The flat band is covered with felt and leather, and is stitched to a band of webbing, which surrounds the body and is buckled on the opposite side in front.

Straps Required.

The measurements for straps may be taken when the patient first attends to have the bucket moulded on the stump.

The straps are made from strong webbing. One is made to form a waist belt. (Fig. 10.)

Two vertical straps attached to this are made to buckle with two straps attached to the centre line of the pylon, about 6 inches from the top in front and behind. Elastic webbing is preferable in the back strap to facilitate flexion at the hip-joint.

Two additional straps pointing to the opposite shoulder are fixed to the waist belt in a line taken from a point in the middle line of the front and back of the pylon, 6 inches below the top, the back strap crossing the opposite shoulder and buckling in front.

Below Knee Pylon.

The method of making the pylon for a tibial stump is similar to that of the thigh pylon, with the addition of

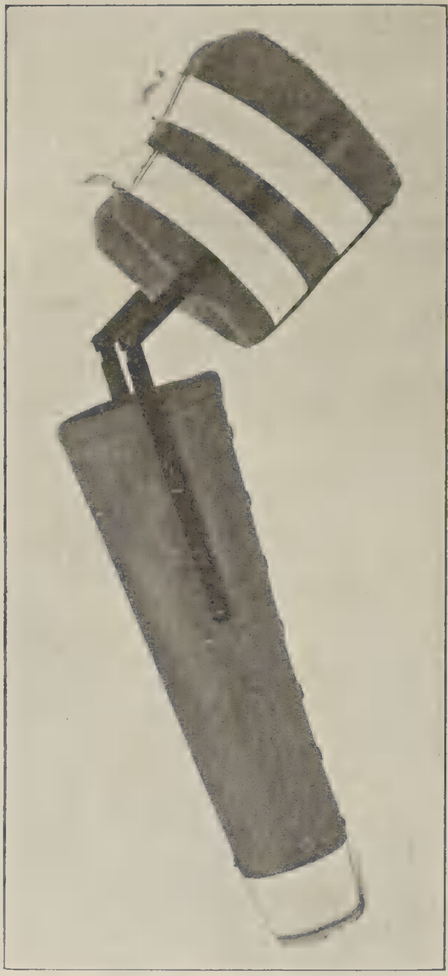
jointed side irons riveted below to the fibre cone and above to a gauntlet, which is made from fibre lined with felt and fastened by straps. (Fig. 11.) In the case of a Symes amputation a small bucket is made and inserted in the fibre cone, which has a larger wooden block fitted and padded with felt to the required height. The rubber for making the top of the pylon can be purchased at a low cost, as can also the rubber pads for the wooden blocks, by buying scrap motor tyre covers and tyre tubes from some motor works.

11



Pylon for a tibial stump, showing jointed side-irons.

Approximate Cost.

The approximate cost is as follows:—

Material.	Quantity.	Price.	
Fibre	4 sq. ft.	3	0
Wooden block	1		9
Rubber heel pad	1		2
Webbing	4 yds.	1	6
Copper rivets and washers	12 of ea.		5
Bifurcated rivets	12		6
Buckles	4		8
Plaster	2 lb.		3½
Glue	¼ lb.		3½
Bandage, gauze	12 yds.	1	6
Leather lining	1¼ sq. ft.	1	10½
Rubber top	21″ × 5″	1	0
Rubber solution	—		4
Flour paste Enamel Screws	—		6
		12	9½

Pelvic bands and side-irons make a slight increase in price.

Owing to the intervals required for drying purposes three days are allowed for the manufacture of the pylon, although the actual time of labour is only four hours.

The type of pylon described above is made at the B.R.C.S. Limbless Hospital, Longford Hall, Stretford, Manchester. It is comfortable to wear. The men like it and walk well in it.

For assistance in the work of its evolution I must thank the members of the Ford Motor Company's Ambulance Division, especially Mr. George Holt, whose ideas in experimental work have helped to bring about results satisfactory to the limbless men themselves. Also to Mr. Philip Buckley, limbless surgeon, and Dr. Wheeler Hart, county director, B.R.C.S., whose enthusiasm in the work was most encouraging.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

◆

THREE CASES OF

ACUTE PANCREATITIS.

By G. Percival Mills, F.R.C.S. Eng.,
ASSISTANT SURGEON TO THE GENERAL HOSPITAL, BIRMINGHAM; SENIOR SURGEON TO THE ROYAL ORTHOPÆDIC AND SPINAL HOSPITAL, BIRMINGHAM.

As the pre-operative diagnosis of acute pancreatitis is very difficult, the following three cases may be worthy of record.

Case 1.—M. R., female, 35, single. Previous history not known. On April 20th, 1919, after mid-day dinner, complained of pain in upper abdomen and back, which gradually increased during afternoon. At 10 P.M. the pain became agonising and during night patient was rolling about on the floor and praying for death. Vomited repeatedly. Pain and vomiting continued next day though pain was less severe. I saw patient on the evening of the following day with Dr. S. Shaw. She was obviously desperately ill. Temp. 97° F. Pulse 140 and very small. Resp. 20. Abdomen rather distended but moving slightly on respiration. Attempts at deep respiration or any movement of the abdomen caused agonising pain. There was tenderness over the whole abdomen, especially in epigastrium and right and left hypochondria. There was rigidity over the upper segments of both recti—more marked on the right. Dullness on percussion in both flanks. Liver dullness normal and no jaundice.

Diagnosis.—A provisional diagnosis of perforated gastric ulcer had been made, but the following points led us to reconsider this: (1) The type of pain, causing the patient to roll about on the floor; (2) the intense pain across the back; (3) the repeated vomiting; (4) though less important, the absence of free gas in the peritoneum was unusual in such an advanced case. These facts led me to suggest, though I regret to say, not to diagnose, an acute pancreatitis.

Operation (about 36 hours after onset).—Right paramedian incision above umbilicus. There was a quantity of blood-stained fluid in the peritoneum. The pancreas was swollen, and the peritoneum covering it enormously thickened by œdema. No fat-necrosis. There was a large calculus in the common duct, and the gall-bladder was full of small calculi. The gall-bladder was opened and all the calculi, including the one in the common duct, removed through it. The peritoneum was mopped dry, the gall-bladder drained, and a drainage-tube put in the pelvis. The patient was, of course, acutely ill, and the operation took 21 minutes. She was better for a time, but died the following day. No post-mortem was permitted.

CASE 2.—Mrs. H., 35, had been suffering from epigastric pain and flatulence after meals for a week. At 11.30 P.M. on June 14th, one hour after a meal, she was suddenly seized with violent epigastric pain and pain across back, which continued without cessation all night. Vomited five or six times. She was seen by Dr. B. Tomkys at 8 A.M. He found her in acute pain, with a temperature of only 99·2° and pulse of 92. The abdomen was not distended and moved on respiration, but respirations were very shallow as patient was afraid to take a deep breath. The whole abdomen was very tender, and there was tenderness across the loins also. When I saw her at 11 A.M. the condition was as above, but the pulse had risen to 100, there was definite though slight abdominal rigidity, and the patient had vomited again. The liver dullness was normal and there was no sign of fluid in the flanks.

Diagnosis.—Dr. Tomkys, who had been present at our discussion of the previous case, suggested that this might be another acute pancreatitis. I agreed, but was not convinced that we could exclude a perforated gastric ulcer. The pain was different in type from that in the last case. She lay still and was positively afraid to move.

Operation (about 12 hours after onset).—Paramedian incision above umbilicus. Peritoneum normal. No fat-necrosis. Single stone in gall-bladder the size of hazel nut. Head of pancreas swollen and hard; peritoneum over it greatly thickened and œdematous, as also was all the tissue round the common bile-duct, so that exploration was extremely difficult. The stone was removed from the gall-bladder, which was drained, and the common bile-duct was also opened and drained. A cigarette drain was also inserted down to the opening in the duct in case of leakage. During convalescence drainage of bile was very free from the tube, which had been stitched into the common duct. Progress was uninterrupted, and in three weeks patient was getting about and taking ordinary diet. A week later, however, she had another attack of pain with nausea and considerable abdominal tenderness. When I saw her on the following day she complained of stabbing pain in the left hypochondrium on taking a deep breath. Temp. 100°, pulse 96, and there were no abdominal signs. The next day pulse and temperature were normal and the pain was gone. There was no excessive fat in the stools (12·9 per cent. of dried fæces). She was put on a modified diabetic diet and was quite well in a few days. Her doctor recently informed me that she has been quite well ever since.

CASE 3.—A. T., female, 48. Seen June 15th, 1919, at General Hospital, Birmingham. Twenty-four hours previously attack started suddenly with pain in the epigastrium and between the shoulders, associated with copious eructation of gas and bilious vomiting. Pain was greatly increased on trying to take a deep breath. Later on there was some pain in right iliac fossa also. For ten years has had occasional attacks of pain between the shoulders with much flatulence and vomiting of bile. Last attack three years ago. On examination the patient looked seriously ill. Temp. 101°, pulse 104, and resp. 48. The respiratory movements were very shallow, but abdominal movement was present. There was distinct tenderness in the epigastrium, but to a slight degree in the right iliac fossa also. There was slight rigidity of both upper recti. Liver dullness normal and no free fluid.

Diagnosis.—Probable acute pancreatitis.

Operation (24 hours after onset).—Paramedian incision above umbilicus. Peritoneum normal. No fat-necrosis. Gall-bladder full; no calculus. Pancreas swollen and hard, the peritoneum over it œdematous, and the tissues round it and the lower part of the common bile-duct fixed and hard as though by a cellulitis. On carefully examining the head of the pancreas it was seen that there were about half a dozen ashy-grey necrotic patches, about the size of grains of corn, just under the œdematous peritoneum. The peritoneum was incised over these and a cigarette drain put down to the site. The gall-bladder, which contained bile, was also drained. Convalescence was uneventful, the pulse and temperature were normal on the third day, and the patient went home in three weeks. I heard from her on Oct. 31st, four and a half months later. She had had no more pain and was much better in her general health.

Remarks.

Without wishing to dogmatise on an experience of three cases, the following conclusions suggest themselves:—

1. These are probably early cases which would go on to gangrenous pancreatitis. In one case the gangrene had commenced—e.g., the necrotic patches in the pancreas.
2. Early drainage of the biliary tract will cure them. The first case was hopeless from the start.
3. Biliary calculi need not necessarily be present.
4. Points in diagnosis: (*a*) Thin middle-aged women—not fat men as is often stated; (*b*) general resemblance to perforated gastric ulcer in the sudden onset of acute abdominal pain after a meal, with abdominal tenderness and rigidity, low temperature, rapid pulse, and shallow breathing. But (1) pain is across back as well as in epigastrium, and may at first be of the colicky type; (2) vomiting is repeated and may be associated with much eructation of gas; (3) the rigidity in the early stages is not nearly so marked as in perforated ulcer.

Finally, it is worth noting that, though one would expect a trace of jaundice, it was not present in any of the three cases. Its absence, therefore, should not influence the diagnosis of acute pancreatitis.

TRAUMATIC RUPTURE OF INTESTINE WITHOUT EXTERNAL INJURY.

BY GERTRUDE M. A. HERZFELD, M.B., CH.B. EDIN.,

ASSISTANT SURGEON, ROYAL HOSPITAL FOR SICK CHILDREN, EDINBURGH; LATE SENIOR HOUSE SURGEON, BOLTON INFIRMARY.

FIVE of these cases have occurred in Bolton Infirmary during the last two years, and, in view of the recent interesting papers by Mr. W. H. Battle and others on this subject I think the following notes may be worthy of record:—

CASE 1.—P. H., a well-developed lad of 14, was admitted at 7.30 P.M., June 24th, 1918, as a case of acute appendicitis. Temp. 101°, pulse 120. At 8.30 P.M. on the previous day, while out walking, he had stumbled and fallen heavily forwards, and a golf-ball in his right-hand coat pocket was driven into the right iliac fossa, causing such severe pain that he had to be assisted home. Shortly after reaching home he had vomited, and he had complained of constant abdominal pain up to the time of admission. I opened the abdomen at 9.30 P.M., 25 hours after the accident, by an oblique through-and-through incision in the right iliac fossa, and found a generalised peritonitis and a rupture of the ileum half an inch long, 2 feet from the ileo-cæcal valve. The appendix was normal. In addition, there were present a Meckel's diverticulum and a congenital horse-shoe kidney, the right half of which lay in the right iliac fossa, and was joined to the left half, lying partly in the pelvis, by a transverse band about 1½ inches broad. The perforation was sutured in two layers, and drainage-tubes were passed into the pelvis, kidney pouch, and right iliac fossa. The patient developed a patch of pneumonia on the tenth day, but made a good recovery and went home six weeks after operation. He is now well.

CASE 2.—G. L., male, 42, admitted Feb. 8th, 1918. Hit in the abdomen by an iron girder. Laparotomy six hours later. Lower end of ileum torn completely across, cæcum bruised. Ileum anastomosed to transverse colon. Death five hours later.

CASE 3.—A. L., male, 45, admitted Feb. 15th, 1918. Struck in right iliac fossa by a heavy plank of wood. Laparotomy four and half hours later; small rupture of anterior wall of cæcum; suture with drainage. Recovery.

CASE 4.—J. H., male, 17, admitted August 8th, 1918. Jumped over a counter on to a broom-handle which broke, and the sharp end of the lower fragment was driven through the anus into the rectum. Laparotomy eight hours later. Perforation of rectum and of ileum; suture with drainage. Death next day.

CASE 5.—G. C., male, 43, admitted Oct. 1st, 1919. Run over by a motor charabanc. Laparotomy six hours later. Complete tear of upper ileum; end-to-end anastomosis; no drainage. Recovery.

Remarks.

Apart from freak cases, like Case 4, or the tear which occurs at the attachment of the ligament of Treitz after a drop from a height, traumatic rupture of the intestine is caused either by (1) a heavy blow or crushing injury—e.g., Cases 2, 3, and 5; or (2) a sharp, not necessarily heavy, blow, which takes the abdominal muscles unawares (Case 4); in both the intestine is crushed against bone, either vertebral column or ilium.

The early diagnosis of these cases is often very difficult. The immediate signs of ruptured bowel, quâ rupture, are practically nil. Pain, tenderness, vomiting, flank and liver dullness, are signs which tend to confuse rather than clarify the issue. Especially is this the case where the lower thorax has been crushed as well. The pulse-rate and abdominal rigidity are of little value as early signs, but a rising pulse-rate and increasing rigidity call for immediate operation.

When in doubt it is probably wise to operate. The surgeons's point of view should surely not be "Is there evidence of ruptured intestine?" but "Is there sufficient evidence to justify exploration?"

If peritonitis with its concomitant distension, &c., is established, the operation follows the usual lines for that condition; in an early case, however, it is, I think, most important to begin with a sufficiently long incision; a small incision which subsequently has to be enlarged leads to waste of valuable time and maybe to faulty procedure. I make a paramedian incision, choosing the side according to the history or symptoms, and make it long enough to allow of a preliminary inspection before manipulation. Inspection often reveals the location of the injury and allows of adequate packing before disturbance of the abdominal contents. If, however, the first opening of the peritoneum is a mere nick, a careful watch can be kept for escape of gas; the abdominal wall should not be drawn forcibly forward at the moment of incision, as in an ordinary case, but allowed to lie naturally, while a small fold of peritoneum is lifted with forceps and nicked; otherwise one may be deceived by the inrush of air.

A resection should not, I think, be necessary; I have found the best procedure to be a lateral anastomosis between two separate tears, with, if need be, approximation of the loop. The peritoneal cavity should not be flushed out, but gently cleansed by wiping. When drainage is indicated the pelvis may be drained by a suprapubic stab, and one or other kidney pouch, but drainage should be avoided if possible.

The closure of the abdomen with through-and-through sutures of silkworm gut is especially important where the patient's general condition is bad. Wounds so closed appear to be no more liable to ventral herniæ than where suturing in layers has been done

The chief points in the after-treatment of my cases have been the Fowler position, Murphy drip, and Lane's cannulæ in the axillæ.

A NOTE ON THE INTRAVENOUS ADMINISTRATION OF MERCURIC IODIDE IN THE TREATMENT OF SYPHILIS.

BY R. L. SPITTEL, F.R.C.S. ENG.,
SURGEON, GENERAL HOSPITAL, COLOMBO.

IT is a safe statement to make that the medical world is agreed that "606" and "914" (whatever trade name they go by) are the drugs par excellence in syphilis, but it is also perhaps true to say that the majority of those with a large experience of syphilis are not disposed to rely solely on those preparations, and prefer to strengthen their action with mercury and iodides—drugs which have stood the test of time.

Salvarsan, given as it most often is by the intravenous route in a dose not far below the point of tolerance, has the advantage of the older drugs, in that these are given as a rule in smaller doses and by less direct routes. Iodides are given almost exclusively by the mouth; mercury by the mouth, inunction, intramuscular injection, and, by some, intravenously, but in small doses. Up to the present the most popular method of giving mercury with a view to reinforcing the action of salvarsan is by small weekly intramuscular injections of grey oil or calomel cream.

I here report a method of administering mercury and iodide, which I have found superior to any other. When, at the beginning of the war, there was a likelihood of a shortage of salvarsan, I experimented with arsenic, mercury, and iodide, taking as my working hypothesis dosage to the point of tolerance by the intravenous route.[1] An experience of over 4000 of these injections, during a period of four years, convinces me that the solution here advocated has only to be given a trial for its worth to be established. It is a valuable adjunct to the treatment of syphilis with salvarsan; the combination establishing a cure (as gauged by Wassermann tests, provocative and otherwise, at varying intervals) more quickly and permanently than by any other method I know.

Composition of the solution.—The solution has the following composition:—

Mercuric iodide...	50 gr. (3·24 g.)
Sodium (or potassium) iodide	8 dr. (28·42 g.)
Phenolphthalein (0·5 % solution) ...	20 ♏. (1 c.cm.)
Sodium hydrate (25 % solution) ...	about 2 dr.
Distilled water ... ... to	40 oz. (1000 c.cm.)

Before the addition of sodium hydrate the solution is acid; it has to be rendered slightly alkaline; the phenolphthalein it contains is both an index of correct alkalinity and a colouring agent. The sodium hydrate should be added last and gradually; once the neutral point is reached it is put in drop by drop until a brilliant and clear pink colour is obtained. The solution keeps indefinitely, and when prepared under aseptic precautions and stored in a glass-stoppered bottle is always ready for use. If kept too long it tends to become decolorised (probably from the presence of hydriodic acid); the addition then of a few drops of the odium hydrate solution quickly restores the necessary lkalinity and colour.

---

[1] Practitioner, October, 1918.

Mode of administration.—The dose for an adult is to 12 c.cm. given intravenously with a 20 c.cm. or, etter, a 30 c.cm. syringe. The required dose is filtered ff through aseptic cotton-wool and drawn into the yringe, which is then filled to its full capacity with trained sterile or distilled water. This further ilution, with at least an equal quantity of water, referably more, is necessary to prevent pain and hickening of the vein; a 30 c.cm. syringe is therefore ecessary for the larger doses. Should any of the olution escape into the tissues outside the vein a ender induration results, as with salvarsan. Unless xceptionally well borne a dose of 12 c.cm. need not be xceeded.

Reaction.—The injection is tolerated well. Heavy loses may cause chill, fever, malaise, and abdominal ains with diarrhœa (sometimes bloody), and griping; ut there is scarcely any reaction when an initial dose f 7 or 8 c.cm. is given and gradually increased by or 2 c.cm. at a time, according to tolerance. Gingivitis nd salivation give the clue to quantity. Heart and idney disease need not stand in the way of careful losage.

Results.—The rapidity with which these injections ause the disappearance of syphilitic lesions is indeed ratifying; the results are not only far quicker than hose obtained with mercury and iodides given by any ther methods, but often even a single injection produces an effect almost as phenomenal as salvarsan. In erve syphilis especially some of the finest results are btained; this is not to be wondered at when the bsorptive action of iodides is remembered.

Courses of treatment.—The number of injections and he interval between them vary, of course, with the articular case. An ordinary case of secondary syphilis nay be treated with five or six injections each of alvarsan and mercuric iodide, given at intervals of from even to ten days alternately, in varying sequence or in uccessive courses. Often after such a series a negative Wassermann reaction is permanently obtained; if not, urther courses are given to meet particular needs.

Syphilis is not a disease with which any risk should be taken; and our knowledge of blood reactions not being final, it is hardly prudent to pin our entire faith on their infallibility. It is well, therefore, to safeguard the patient by prescribing mercurial treatment by mouth or inunction (measures which have the advantage that the patient can carry them out at home) for periods varying from 8 to 12 months, according to the demands of the case. Some such routine course as the following may be begun from the day the patient comes for advice, and be carried through despite the injections. Mercury, in the form of grey powder, is to be taken for six weeks; this is followed by an interval of one month, in the middle ten days of which an iodide mixture is given, e.g.:—

℞	Potass. iodid.	5 to 20 gr.
	Liq. arsenicalis	4 ♏
	Extr. sarsæ liq.	1 dr.
	Syrup. glycerophosph. co....	1 dr.
	Infus. cinchon. ... ... ad	½ oz.

Sig. To be taken in a glass of milk or water twice a day.

These oral courses of mercury and iodide are to be continued for about a year.

Colombo.

VOLUNTARY CORPS OF NURSES AT NEWPORT.—At a recent meeting of the Newport Town Council the Council approved a suggestion from the medical officer of health that the ladies who had aided the nurses in the war years should be asked to form a voluntary corps to be available for service in case of outbreak of influenza. A ward has been set apart in St. Michael's Hospital for influenza patients.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

BACTERIOLOGY OF TYPHUS AND RELAPSING FEVER IN MESOPOTAMIA AND NORTHERN PERSIA.

A MEETING of this section of the Royal Society of Medicine was held on Jan. 27th, at which a paper was read by Dr. W. H. WILLCOX on Typhus and Relapsing Fever in Mesopotamia and Northern Persia. This paper was reported in THE LANCET last week.

Dr. J. C. G. LEDINGHAM showed a chart illustrating the course of the typhus and relapsing fever prevalences from October, 1917, to December, 1918, in relation to the meteorological conditions peculiar to Mesopotamia. The correspondence in time and shape of the two curves of lice-borne diseases was most striking. Both diseases started from small beginnings in the last quarter of the year and both attained maximal prevalence in April, thereafter to fall abruptly to minimal or zero figures in the hot season. The volume of the epidemics was mainly Indian, the British factor forming but an insignificant portion. During the rise of the two prevalences, when one might expect optimal conditions for the propagation of the disease by lice, the mean daily maximum temperature was gradually rising from 60° to 75° F. The relative humidity reached its maximum in January and then gradually fell, to reach its minimal of 10–25 per cent. in July, the hottest month of the year. After April conditions became increasingly unfavourable for the louse, the very high temperature with rapidly diminishing humidity interfering with breeding, whilst the hot weather led also to shedding of superfluous clothes and to excessive sweating, and consequently deprived the louse of comfortable shelter.

Bacteriological Diagnosis.

He then dealt with bacteriological diagnosis. In the case of relapsing fever this was entirely determined for notification purposes by the demonstration of the spirochæte. No case was returned as relapsing fever in the absence of a microscopic finding, and from an analysis of the laboratory findings there was a very close correspondence between the laboratory returns and the official figures. The microscopic diagnosis was a simple and straightforward procedure. It was not determined whether there were any other than the usual species of spirochæte present, for this was a difficult matter and the necessary facilities were not available. There was no reason to suppose that any insect other than the louse played the part of vector. The diagnosis of typhus fever was until the last quarter of 1918 on a clinical basis, supported by results of blood culture to exclude typhoid or paratyphoid, and microscopical examination of blood films to exclude relapsing fever and malaria. The fact that the onset of typhus or any other intercurrent infection might cause malarial parasites to appear in the peripheral circulation in a quiescent malarial subject and thereby confuse the diagnosis had to be borne in mind. In the last quarter of 1918, when typhus fever again appeared, an opportunity was afforded of supplementing the purely exclusive methods of blood culture and microscopic examination of films by the employment of the Weil-Felix reaction. A culture of the proteus strain X 19, now used almost universally for this test, was available. There was no question but that, although the actual *materies morbi* of typhus fever was still unsettled, the bacteriologist was in a position to give valuable help of a positive nature in its diagnosis. The tests carried out at the Central Laboratory, Baghdad, by Captain T. R. Bowen, R.A.M.C., under the superintendence of Major F. P. Mackie, I.M.S., had impressed him greatly and had almost persuaded him that an organism which reacted so strongly and regularly to the sera of typhus patients could be no other than the actual *materies morbi*. This was highly improbable, however, and the phenomenon was capable of other explanation.

New Organisms.

As early as 1883 there was a record of the finding of motile spirilla in typhus blood, and since then scarcely a year had passed without some claimant coming forward with a new organism. Cocci of various kinds, including streptococci, bacilli, diplobacilli, spirilla, spirochætes, and also organisms of a more protozoal structure had been incriminated. Doubtless many of the findings were ordinary contaminations, yet the fact had to be reckoned with that at least some of the organisms recovered from typhus cases represented genuine blood invaders. Of the more recent of these might be quoted the cocci recovered by W. J. Wilson, of Belfast, in 1910. Very similar cocci of the *S. viridans* type were recovered by Penfold from the blood of typhus cases in Ireland in 1916, and also by Miss Muriel Robertson. Penfold had been able to cultivate the same coccus from monkeys inoculated with typhus blood, and with pure cultures of this coccus he noted a pyrexial phase in inoculated monkeys. Miss Robertson immunised monkeys with the coccus, but they did not prove to be immune when tested with virulent typhus blood, and reacted similarly to the untreated controls. In 1909 Horiuche recovered from the urine of some cases of typhus in Manchuria an organism which was agglutinated by the sera of typhus patients only, and that in high dilution. Wilson's experience in 1910 was similar. In 1916 Weil and Felix recovered from the urine of a typhus patient organisms of the proteus type, which were agglutinated in high dilution by typhus sera only. Later they recovered another proteus which they named X 19, and which was found to act still better in this test. During the last three years an enormous literature had accumulated on the diagnostic value of what was now called the Weil-Felix reaction, and its probable significance. Of its diagnostic value no doubts had been uttered. The serum of 90 to 100 per cent. of typhus cases would give this reaction in high dilution at some stage of the disease. Reactions had been obtained with dilutions up to 1 in 30,000, whilst control sera either did not agglutinate the organism at all, or, in a small proportion only, reacted with it in dilutions not exceeding 1 in 50. About 50 per cent. of cases would give the reaction by the fifth day, while by the tenth day practically all cases would react. A negative reaction was sufficient to suggest a diagnosis other than typhus fever.

Proteus X 19 had recently been recovered from the blood in a varying percentage of cases. Thus Zeiss got proteus from the blood in 19 out of 278 cases, but never from the blood in 167 examples of other diseases. Dienès got proteus from the blood in 30 per cent. of 14 cases. Others had been less fortunate, and Felix, in Asia Minor, failed to recover the organism in a single case of 250. Proteus X 19 was highly pathogenic to guinea-pigs and mice, but did not produce in these animals the pyrexial phase which follows the inoculation of typhus blood. Nor did immunisation with proteus render animals immune to typhus blood. The Weil-Felix reaction came most probably into the category of paragglutination phenomena from which, however, it differed in one material point—the permanence of the agglutinability of proteus with typhus sera in spite of long-continued laboratory growth. One could only assume that a particular proteus had become so serum-impressed as to retain its agglutinability for an indefinite period, and to serve as a test organism for the polyagglutinating capacity of typhus serum. While knowledge had increased of typhus diagnosis it had also increased of the part played by the louse. If the louse be admitted to be the only vector, it was necessary in the future to demonstrate any presumed typhus organism in the louse or its excreta. Accordingly the adherents of Rabinowitsch's organism, of Plotz's anaerobic organism, and of proteus X 19 had been coming forward to identify their respective organisms with the Rickettsia bodies discovered in infected louse excreta by Ricketts in 1909 and later confirmed by Rocha-Lima and Prowazek in 1916. But the Rickettsia bodies had not yet been grown, though if they had anything in common with the organisms identified with them they should have been readily cultivated.

Conclusions of French and American Investigators.

Dr. J. A. ARKWRIGHT, in the course of a review of the bacteriology of typhus fever, said that the French investigators in Tunis and the Americans working with the Mexican and New York forms of the disease arrived at the following conclusions:—

(1) The blood of human cases of typhus is infective for monkeys, and the disease can be transmitted by the blood from monkey to monkey, from monkey to guinea-pig, from guinea-pig to guinea-pig, and back again to the monkey after many passages through the guinea-pig.

(2) The virus can be conveyed by the plasma and by the serum obtained by centrifuging defibrinated blood, but not so readily by clear serum taken off the clot.

(3) The virus is destroyed by heating to 55° C. for 15 minutes and by drying in vacuo over sulphuric acid.

(4) It does not pass through an efficient Berkefeld filter in sufficient amount to cause an infection.

(5) Lice which have been infected on a human case or on a monkey can apparently convey the disease to a monkey by their bites, and inoculation of their gut contents by scarification or subcutaneous injection will infect a monkey or a guinea-pig.

(6) Typhus may be transmitted experimentally by either pediculus corporis or pediculus capitis.

(7) The experiments of Ricketts and Wilder point to a necessary incubation period in the louse before it becomes infective, but the evidence is not very complete, and at this period different observers did not agree on this point.

Cantacuzene had recently narrated instances of 15 medical men who had all been infected by the bites of one, or at most two, lice, the exact time of the biting having been accurately ascertained in some instances. The incubation period was usually 8 to 10 days, but in one case as long as 23.

The Virus of Typhus in the Louse.

The most advanced phase in our information about the virus of typhus was concerned with it as it exists in the louse. Very small bacillus-like bodies known as *Rickettsia prowazeki* were first described by H. T. Ricketts and Russell M. Wilder in April, 1910, as occurring in the blood of patients and in the body of the louse. In blood films of patients taken on the seventh to twelfth day of the disease they invariably found a short bacillus of the hæmorrhagic septicæmia type, which stained either solid or only at the poles. They estimated that they were between 300 and 2000 in 1 c.cm. of blood. In the fæces and intestine of the louse they were much more numerous. They also described and differentiated these organisms from other bacteria found in smears of lice. Our knowledge of these minute organisms had been largely advanced by Rocha-Lima in Poland in 1914–15, who first worked with Prowazek in Serbia in 1913, where both caught typhus fever, of which Prowazek died. Rocha-Lima rediscovered these forms in the louse, and Prowazek considered that they were the same that he had seen and described in the blood of patients when working at typhus in Poland in 1913. Rocha-Lima had two great advantages, for he was associated with a highly skilled entomologist, Sikora, who had made a speciality of pediculi, and he had the additional knowledge, due to Nicolle, that most guinea-pigs are susceptible to the virus of typhus. He was primarily a protozoologist, and was inclined to regard the organisms as protozoa. By collecting lice from patients and other persons, and also by feeding normal lice from Hamburg and then examining them microscopically by means of sections and smears of the gut, and also by inoculating guinea-pigs with their gut contents, he was able to determine the following points:—

(1) When pediculi were fed for from five to eight days on a typhus patient, preferably between the second and tenth day of the illness, a proportion of them were found to contain very large numbers of Rickettsia bodies, often in apparently pure culture, and these were found, not only in the lumen of the gut, but also in the epithelium of the mid-gut in masses. He found that 95 per cent. of the lice from advanced cases of the disease were infected. Before the fourth or

ifth day from the commencement of feeding the lice did not show these forms.

(2) The lice so infected were able to give the disease to guinea-pigs when crushed and injected subcutaneously. Even part of the gut of one louse was sufficient.

(3) Lice fed after the fall of temperature did not contain these bodies, and were not infective.

(4) Lice kept at a temperature of 23° C. neither became infective nor contained Rickettsia bodies, whilst a temperature of 32°–34° C. was the optimum for producing both these conditions.

(5) For lice to become infected it was not necessary that they should continue to feed on a febrile patient. If after one or two feeds in one day on a patient at the height of the disease the lice were subsequently fed on a convalescent, they became infected, and the convalescents were immune and ran no risk of infection.

(6) If lice were fed daily on a patient the proportion of those infected rose as time went on, and almost all were infected after ten days. Lice once infected usually remained so until they died, but sometimes appeared to get rid of the infection and recovered. The lice used were derived from a source free from typhus or were bred in captivity and previously fed only on healthy persons.

(7) He was unable to demonstrate the inheritance of infectivity or of the Rickettsia bodies in the louse, except in one experiment which he thought was successful.

(8) No attempts to cultivate the Rickettsia bodies from pediculi had succeeded.

Other workers had confirmed these results with some divergence of opinion in matters of detail. He found that lice fed on healthy men or on those suffering from other diseases rarely showed Rickettsia and never the intracellular form.

The most serious criticism of the significance of the rôle played by Rickettsia came in part from those who were most impressed by its importance, for Ricketts, Rocha-Lima, and Otto and Dietrich all found these bodies or forms suggesting their presence in lice believed to be normal, though they are usually described as rare. Nicolle and Brumpt, however, believed that they occurred so frequently in controls as to discount their importance. This conflicting testimony can be explained by the great difficulty or even impossibility of being sure of the nature of very small diplococcal bodies seen in a film when only a few are present, and by the existence of at least two kinds in human lice. These have been named by Rocha-Lima *R. prowazeki* and *R. quintana*, the latter being as clearly and closely associated with trench fever as is the former with typhus. It seemed very probable that the irregularities in the occurrence of Rickettsia could be attributed to trench fever infections. Dr. Arkwright had been able to see some patients with typhus in Ireland, and to collect lice from their clothes and feed normal lice on them. Rickettsia were found in the lice and their excreta in a few specimens by him in collaboration with Bacot and Duncan, but no doubt the lice were kept at too low a temperature for free development of Rickettsia. However, a monkey was infected by injecting 20 lice, and the infection was passed on to two other monkeys and to guinea-pigs. It was also shown that the monkey-louse became infected. Of 93 specimens from 3 infected monkeys, 38·7 per cent. were infected, and of over 100 from healthy monkeys none showed these forms.

Microscopical Pathology of Typhus.

An interesting observation had recently been made in the microscopical pathology of typhus. Fraenkel, Jaffe, and others had described minute nodules of cellular infiltration in the course of the arterioles, and changes in their vessel walls in various organs, in the skin lesions, and especially in the mid-brain, frozen sections of which had been stated to be sufficient to establish the diagnosis. Rickettsia had been described in these nodules. Otto and Dietrich had described agglutination of Rickettsia by the blood of typhus convalescents. Experiments with a view to producing a prophylactic vaccine or therapeutic serum had not yet given very striking results, though Nicolle and Blaizot had immunised horses with extracts of organs of infected guinea-pigs. Vaccination experiments with the heated blood of patients or with virus from other sources treated to make it innocuous, had not given encouraging results.

Among subsequent speakers Dr. WILLIAM HUNTER spoke of the accurate description of typhus fever given by Murchison, who had got so near to the mode of transmission as to recognise that actual touch was necessary. He had stated that the incubation period was from 10 to 12 days. In Serbia a remarkable accession of cases occurred exactly on the eleventh day after movement of troops was begun and as remarkable a subsidence on the same day after movement was restricted.

Dr. A. G. PHEAR said that when visiting hospitals in Southern Russia, Northern Persia, and the Caucasus, he found that no treatment was considered necessary for relapsing fever, all the patients getting well without it. This pointed to a relative immunity in those peoples among whom the disease was endemic.

SECTION OF SURGERY.

CONGENITAL DIVERTICULUM OF THE COLON.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 4th, Sir JOHN BLAND-SUTTON, the President, being in the chair, when Mr. GARNETT WRIGHT read a paper on Congenital Diverticulum of the Colon. Congenital diverticula were, he said, extremely rare in connexion with the large bowel, and he thought that a case which had been under his care was worthy of record as being almost unique.

The patient was a married woman, aged 27. She had suffered from constipation and abdominal pains ever since she could remember. The griping pains and constipation had steadily increased, and for two or three days before admission to hospital constipation had been absolute and she had vomited once or twice. On examination there was definite visible peristalsis, and although the bowels were evacuated the griping pains and visible peristalsis continued. The abdomen was opened and the whole of the large intestine was found to be greatly dilated and the meso-sigmoid occupied by a cystic swelling. A longitudinal band was found to bifurcate at the commencement of the sigmoid colon, and it was evident that a diverticulum was originating at this point. It left the meso-sigmoid at its lower end and turned upwards behind the posterior parietal peritoneum, and ended in a large sac on the posterior abdominal wall behind the stomach. Complete colectomy was performed, and the ileum united to the lower part of the ileo-pelvic colon by lateral anastomosis. The patient appeared to be progressing fairly satisfactorily until the ninth day, when the temperature fell to 97° F. and vomiting set in. The abdomen was reopened, when it was found that suppuration had occurred in the anastomosis, which had given way. The patient died that evening.

Description of Specimen.

The specimen removed consisted of the termination of the ileum and the large intestine from the cæcum to the upper end of the rectum, together with the diverticulum. The colon was in a condition of moderate idiopathic dilatation, and in the recent state measured 8 ft. in length. The diverticulum, which when fresh was 37 in. long, commenced at the upper end of the sigmoid loop of the colon, running at an acute angle downwards, and entering between the layers of the meso-sigmoid. Here it occupied the concavity of the sigmoid colon and became of a very large size, being much greater in diameter than the bowel. On reaching the end of the sigmoid loop the diverticulum separated from the colon, to which up to now it was intimately adherent, and, narrowing abruptly, passed from between the layers of the meso-sigmoid to lie behind the posterior parietal peritoneum. Here it turned upwards and expanded into a large blind sac, reaching a position on the posterior abdominal wall behind the stomach, and ending in a small button-like projection. In the recent state the circumference of this portion of the diverticulum was 17 in. To facilitate description it may be said that the first part of the diverticulum was about 6 in. long; the second part was that which lay between the leaves of the meso-sigmoid; the third part was a blind sac, entirely retro-peritoneal in position.

The connexion of the tæniæ with the diverticulum was very interesting. The tænia libera was continued from the descending colon into the sigmoid, and did not reach the diverticulum at all. The tænia omentalis bifurcated at the commencement of the diverticulum, one limb descending into the sigmoid and the other running off at an angle to reach the anterior surface of the diverticulum. Here it gradually widened out, losing its band-like appearance, and forming a fairly uniform longitudinal coat, though the main mass of the fibres could still be seen near the convexity of the diverticulum. The tænia mesenterica was continued from the descending colon directly into the posterior surface of the diverticulum, and widened out in a similar manner to the band on the anterior surface. It had no connexion with the sigmoid colon. The blood-supply of the diverticulum was derived from the inferior mesenteric artery, which was of large size.

When the peritoneal sac was dissected away it was seen that the colon and the first and second parts of the diverticulum were intimately blended. Muscular bands could be seen running from one to the other; the septum between the two was common to both and consisted of circular muscle fibres with mucous membrane on each side.

Structure of the Diverticulum.

The muscular coats consisted of an outer longitudinal, which, in the first part, was represented by the tæniæ above described, and an inner layer of circular fibres. Where the colon and diverticulum fused only circular fibres could be distinguished. The inner coat consisted of mucous membrane of the usual large intestine type, the epithelial lining being continued into the button-like projection in the apex of the blind sac. From the anatomical structure of the diverticulum it was obviously a congenital abnormality of the hind gut. The blood-supply from the inferior mesenteric vessels proved that the structure was a portion of the hind gut, while nothing but a developmental error could explain the intimate connexion between it and the colon. Professor Arthur Keith had pointed out to him (Mr. Wright) that in the hyrax double colonic cæca were normally present, arising from the transverse colon, in addition to the usually placed cæca. The bands on the colon and diverticulum combined represented the bands of a single primitive intestinal tube. It would appear that the original error in development had been in the form of a split in the primitive hind gut, the septum being placed coronally and running from the centre of the primitive tænia omentalis to the opposite side of the canals. If this were so, it seemed to him to be against the view that the diverticulum in this case was a throw-back to the colonic cæca of the hyrax, as these presumably arose by lateral bands from the intestinal canal. He could arrive at no satisfactory explanation of the phenomenon.

Literature of the Subject.

He had been unable to find more than one or two cases in the literature of a similar nature.

Meckel[1] mentioned a case of a fœtus with two cæca described by Boerhaven in 1757. Grawitz[2] described the case of a man of 55 who died of peritonitis due to intestinal obstruction, in whom a right inguinal hernial sac was occupied by a diverticulum arising from the middle of the ascending colon. It consisted of a double loop of bowel, opening by a common orifice into the ascending colon. The two loops were separated at the fundus, but were fused near the neck of the diverticulum, having an imperfect septum of mucous membrane only between them at this point. Grawitz considered that this diverticulum might have been formed from a loop of bowel being caught in the hernial sac, and a secondary fusion and breaking through of the lumen at the site of constriction.

Lockwood[3] described a case of double descending colon where the lower ends of both limbs were lost in a mass of carcinoma, but gave no anatomical details.

Hedinger[4] described a post-mortem examination on a newly-born child in whom the distal third of the appendix was thickened and nodular owing to numerous small diverticula of the mucosa, some of which reached the muscularis mucosæ only, while others extended through it and produced projections of the serous coat. He considered that these diverticula were congenital.

Black[5] described an enormous multilocular cystic tumour growing from the serosa at the tip of a diverticulum which sprang from the junction of the rectum and sigmoid. He gave no details as to the structure of the diverticulum, but considered it congenital in origin.

Discussion.

Professor ARTHUR KEITH said that he agreed with Mr. Wright in regarding the abnormality as being the result of a developmental reduplication or splitting of the sigmoid colon. Splitting or dichotomy of the buccal or of the rectal ends of the alimentary tract was known to occur, but there had been no clear recognition that a developmental cleavage could affect a limited and intermediate tract such as the transverse colon or sigmoid. Mr. Wright's specimen might be regarded as an example of this exceedingly uncommon type of malformation. Various forms of cleavage or septal formation were known to occur during the development of the alimentary tract of the embryo. The foregut was cleft horizontally or coronally, so that the ventral compartment became the trachea, while the dorsal part formed the œsophagus. Cleavage might occur abnormally, so that the first part of the œsophagus ended blindly, while the second part sprang from the bifurcation of the trachea. Such was not an uncommon congenital abnormality of the œsophagus. The second part of the duodenum might be the seat of another kind of septal malformation—the septum lying transversely across and completely occluding the lumen of the bowel. Another type was represented by a specimen in the Museum of the Royal College of Surgeons. In this specimen a piece of small bowel from an ox had set side by side with it a long sausage-shaped cyst, 17 inches in length, exactly similar to the small bowel in structure, save that it was lined by stratified epithelium. In this case the cleavage of the bowel had apparently taken place in a sagittal plane, for both bowel and cyst lie side by side and are suspended at the free margin of the common mesentery. In Mr. Wright's specimen the cleavage had been on a coronal plane, the primitive sigmoid being split so as to form a dorsal or abnormal sigmoid and a ventral or normal sigmoid colon. Thus we saw that abnormal cleavage might affect several parts of the alimentary tract of the embryo and might take place in a sagittal, coronal, or transverse plane. It must be remembered that a mere point of adhesion between opposite walls of the embryonic gut would, when the embryonic gut was drawn out to form the adult bowel, become a long septum or cleft. In trying to explain such a malformation as had been shown by Mr. Wright it was vain to seek light from comparative anatomy. In no animal whatsoever was duplication of the sigmoid a normal occurrence.

The abnormal parasigmoid of Mr. Wright's case showed a remarkable condition of hypertrophy. The muscular coats had evidently striven to force the fæcal contents out at the cæcal end of the parasigmoid—at least the degree of hypertrophy increased in the passage from the open mouth to the closed end of the abnormal bowel. At the open or proximal end of the parasigmoid the mucous or glandular coat measured 0·8 mm. in thickness; in the neighbouring part of the normal colon this coat had a thickness of 0·25 mm. At the same sites the muscular coats measured 0·95 mm. (0·8 mm. circular coat, 0·15 mm. longitudinal) in the first, and 0·25 mm. (0·2 mm. circular coat, 0·06 mm. longitudinal) in the second. At the distal or cæcal end of the abnormal sigmoid the mucous membrane measured 0·6 mm., and was provided with numerous solitary follicles. The muscular coats at this point measured 3·7 mm.—14 times the normal thickness. The inner or circular coat measured 2·2 mm., and the outer or longitudinal 1·5 mm. The mucous coat was bound rather firmly to the muscular coat, the submucous tissue being densely packed and much reduced in amount. At the cæcal end the muscularis mucosæ was 0·140 mm. in thickness—almost as thick as the outer muscular coats of a normal sigmoid. The inner circular and outer longitudinal coats of the muscularis mucosæ could be clearly distinguished. Throughout the greater length of the parasigmoid there was hardly more than a trace of Auerbach's (myenteric) plexus. This was particularly the case where the muscular hypertrophy was greatest. We know that addition of new muscular fibres in the embryonic gut takes place from the stratum in which Auerbach's plexus lies. It was a remarkable fact that with such muscular hypertrophy as was seen in the distal half of the abnormal parasigmoid Auerbach's plexus should have almost disappeared. Very large isolated ganglion cells occurred at various sites in both circular and longitudinal coats.

The PRESIDENT said that on reading Mr. Wright's account of this rare diverticulum he at once suspected that it was associated with malformation of the colon. The suspicion was converted into a certainty on examining the specimen. It was an example of doubling of the large intestine. The enormous size and the thickness of the affected section were explained by the fact that it served for some years as a reservoir of fæcal material, much in the same way that a section of large intestine served for the retention and accumulation of a retrograde flow of fæces after it had been put out of action by an ileo-colic anastomosis. The portion of the colon thus put out of action in many cases became enormously distended and its walls thickened. The distension and thickening were only equalled by the alterations that took place in the stomach when the pylorus was the seat of chronic, non-cancerous, obstruction. Doubling of the large intestine was a rare malformation. An accessible record would be found in the *Glasgow Medical Journal*, 1912. It was carefully described by Mr. A. Blair Aitken, and it was illustrated by good figures. The transverse section of the pelvic colon resembled the barrels of a double-barrelled gun. Roux de Brignolles discovered a double pelvic colon whilst operating for appendicitis.[6]

APPENDICECTOMY BY A NEW ROUTE.

Mr. R. H. ANGLIN WHITELOCKE read a paper on Appendicectomy by a New Route, in which he described an operation designed for the removal of the vermiform appendix through the right iliac fossa in cases where no general exploration of the abdominal cavity was called for—i.e., in acute cases rather than chronic.

The Incision.

The incision, usually 2½ inches in length, is made ½ inch or less internal or medial to, and parallel with, the anterior superior spine of the ilium, or as near to it as practicable. The anterior superior spine, a constant and definite landmark, easily felt or demonstrated, however obese the patient, forms the centre. The cut is carried above and below this point to an equal extent, and parallel with the iliac crest and spine and the attached Poupart's ligament. The cut at once divides the skin, subcutaneous fascia, and aponeurosis of the external oblique muscles. The fibres of the internal oblique muscle are then incised, taking for a guide the white line which passes almost horizontally across the muscle from the anterior superior spine to the middle line of the body; it is bloodless, and indicates the natural division of the muscle into an upper and a lower section. The transversalis muscle is similarly treated, and through the subjacent transversalis fascia the exploring finger ascertains the precise condition of the underlying peritoneum. In uncomplicated cases, and whenever there is no evidence of suppuration, this fascia, together with the peritoneum, are divided in a direction parallel to the skin incision, medial or internal to the reflexion of the parietal peritoneum on to the iliac fossa, deep to and parallel with Poupart's ligament. Where an abscess is present or suspected it is safer to turn the peritoneum inwards or medial-wards from its reflexion behind Poupart's ligament, and to open it posteriorly from the iliac fossa. When the abdomen is opened the viscus first seen is generally (86 per cent. of cases noted) large intestine, either the first part of the ascending colon or, less frequently, the cæcum.

In a simple or "interval" case the appendix is removed outside the abdomen. The wound is closed in layers with catgut sutures, the skin being brought together with silkworm-gut ligatures *interrupted* so as to allow of the escape of serum. Only a few sutures are required, since there is but little strain on the edges and the muscles tend to fall together of their own accord. When the appendix is so adherent that it cannot be delivered readily with the cæcum through the wound, as in cases of chronic abscess, the safest and easiest plan is to deal with it as a foreign body by detaching the cæcum from its root and burying the stump; the adherent and detached appendix is then seized at its divided end with forceps and pulled gently upon until it comes away. When the inflamed viscus lies in retro-cæcal or retro-peritoneal positions the muscular and mucous portions of the organ may be pulled out with ease from the inflamed and thickened peritoneal sheath, a firm rubber tube of sufficient calibre then being inserted into the track. Drainage is now seldom used except in cases of abscess. Removal of the appendix as a routine, and with it the focus of sepsis and infection, is sound, for it minimises the immediate risks and any tendency to relapse, shortens the period of drainage, or enables drainage to be dispensed with altogether.

Advantages of the Method.

Anatomical.—The anterior superior spine of the ilium is an unfailing landmark, which can readily be felt in all circumstances of life. An incision or scar running through the external oblique muscle within an inch of, and parallel with, its bony origin is practically free from strain, since it lies in a natural groove or fold of the body. The deep muscles—internal oblique and transversalis—are divided where their fibres are thickest and strongest and most capable of bearing strain—i.e., along the line which indicates their natural division into an upper and lower section. As a rule, no blood-vessels are present to require ligature, nor is any muscle nerve liable to be divided. The parietal peritoneum is here thick and taut, and well supported by extraperitoneal fat at its line of reflexion to the iliac fossa, hence it is less likely to approach the skin wound and so predispose to hernia, even after prolonged drainage. Such approximation of the peritoneum towards the skin through the muscles is perhaps the most important predisposing cause of ventral or other forms of hernia. The ascending colon or cæcum is situated in the direct route, so that the surgeon may rely on discovering the appendix at its origin free from the viscus, no matter where its body lies.

Surgical advantages.—The ilio-spinal approach to a great extent prevents the risk of ventral hernia, since the two main factors concerned in the process—pouching of the parietal peritoneum and muscle strain—are almost wholly eliminated or rendered improbable by the anatomical facts already described. The ilio-inguinal route avoids the necessity of involving the general peritoneal cavity while dealing with the appendix. By this route the peritoneum may be opened and an abscess easily reached and evacuated through the iliac fossa without the difficulties and dangers of soiling or infecting the general peritoneal cavity. The route is, therefore, unquestionably safer and in harmony with the principles of surgery. The appendix may invariably be removed at the time of the operation; the necessity for a subsequent operation is thus obviated. When drainage is established through the iliac fossa to the stump of the appendix or even into the pelvis itself, such drainage is simpler and safer than when an abscess is drained through the general peritoneal cavity; an extruded fæcal concretion may also be more readily found and safely extracted. The procedure is simpler and takes less time than the older methods. The ilio-inguinal route of approach, whether for exploration or removal, enables the surgeon to make a fair estimate of the gravity of the case before the peritoneum is opened. When the transversalis fascia is reached, digital palpation makes it possible to determine not only the presence but the precise situation of an abscess. The extra-peritoneal fat in cases of abscess is often considerably thickened and œdematous and offers distinct resistance even in the early stages; hence if the fingers are gently pressed through the fat against the peritoneum, the resistance encountered enables the surgeon to form some idea as to whether the abscess is immediately subjacent or has passed upwards behind or to the outer side of the colon, or downwards and forwards into the pelvis. When the resistance is slight the peritonitis is almost certainly localised, and the peritoneum may be incised at a point *anterior and internal* or medial to its anatomical line of reflexion, so that the general cavity can be opened with but little risk. On the other hand, if the resistance is such as to justify the suspicion of abscess it is safer to turn the peritoneal fold inwards and forwards, to open the abscess *from behind* through the iliac fossa, and then to deal with the appendix or its concretion, and to establish drainage through the opening.

---

[6] Ann. Internat. de Chir. Gastro-intest., Paris, 1914, viii., 19–23. The President had been unable to obtain this journal.

Clinical advantages.—The principal gain lies in the lessening of the period of convalescence. Prolonged drainage is seldom needed, since the actual source of disease is removed at the time, and consequently recovery is usually rapid. When no drainage is necessary the patient may be allowed out of bed as soon as the wound is quite healed (usually from the tenth to twelfth day), and is able to walk soon after.

Disadvantages of the Method.

No satisfactory exploration of the contents of the abdominal cavity can be made. The operation, however, is recommended for the removal of the appendix and not for general exploration. Laparotomy and exploration of the abdomen may be superadded by means of another incision and without detriment. It may be urged that when the mischief in the appendix is insufficient to account for the symptoms entirely, the return of the cæcum after removal of the appendix may be difficult through the small peritoneal opening. If, however, care is taken to make a free opening through the peritoneum to begin with, if the edges are well retracted, and if the exposed bowel is kept warm the difficulty will rarely be formidable and never insuperable. The provision of adequate drainage is felt to be a difficulty with those surgeons who believe that gravity plays an important rôle in abdominal drainage. An abscess in Douglas's pouch may, however, be quite as efficiently drained through the iliac fossa as through the central abdomen, provided that a sufficiently patent though pliable rubber tube is used.

Conclusions.

The operation had been practised by Mr. Whitelocke for over 12 years, and used almost exclusively during the last eight years. Out of 843 consecutive operations performed at all stages of the disease, whether simple or complicated, and at all ages ranging from 3 to 79 in both sexes, there had been in all 18 fatal cases, yielding a mortality rate of 2·25 per cent. In a recent sequence of 117 cases there had been no death, whilst the 118th and 119th had been unsuccessful. As regards remote sequelæ not a single case of hernia or abnormally weak scar had occurred.

Discussion on Mr. Whitelocke's Paper.

In the course of the discussion Mr. H. J. PATERSON said that he thought the small incision was a drawback. It was impossible to obtain adequate exposure of the abdominal contents.

Mr. W. MCADAM ECCLES said that the incision would be disastrous in a case of general peritonitis. Otherwise the method had its value. He agreed as to the occurrence of herniæ after division of the twelfth dorsal and first lumbar nerves.

Mr. R. P. ROWLANDS said that pulmonary embolism was most likely to occur from the 9th to 16th day after operation. He now usually got his patients up on the fifth day. He used to have a case of pulmonary embolism about once a year. He had not now had a case for seven years.

Mr. C. A. R. NITCH, Mr. RAYMOND JOHNSON, and the PRESIDENT also spoke, and Mr. WHITELOCKE briefly replied.

SECTION OF SURGERY: SUBSECTION OF ORTHOPÆDICS.

EXHIBITION OF CASES.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 3rd, Mr. J. MUIRHEAD LITTLE, the President, being in the chair.

Double Ankylosis of the Hip.

Mr. R. C. ELMSLIE showed a case of Double Ankylosis of the Hip in a man aged 51. The condition started in 1917 with an attack of rheumatism. Ankylosis of both hips was now almost complete. He brought the case forward in order to elicit the opinions of the members as to treatment. Excision or arthroplasty was the choice, but he himself favoured excision, as after arthroplasty the flap frequently became absorbed and the condition of ankylosis recurred.

The PRESIDENT agreed that excision was the form of treatment to be preferred.

Mr. E. LAMING EVANS suggested excision of the head of the femur and perhaps a third to a half of the neck, and displacement of the stump upwards so as to get a movable false joint. Such would be better than the discomfort from which the man now suffered, both in walking and in the ordinary functions of life.

Mr. ELMSLIE said that he believed much of the disability which followed excision was due to inefficient after-treatment. An excised hip was, he thought, better than one which was chronically painful, and better than having both joints stiff.

Congenital Absence of the Ulna.

Mr. A. S. BLUNDELL BANKART showed a case of Congenital Absence of the Ulna in a child aged 10 weeks. The child was one of twins; the other was said by the mother to be normal. The right ulna was absent except for a minute portion at the elbow. The hand was slightly deflected to the ulnar side. There was a dimple in the skin over the radius. The right elbow-joint was ankylosed. There was congenital contracture of the right shoulder-joint, the upper extremity of the humerus being adducted and rotated inwards. The whole limb was smaller than the left.

The PRESIDENT remarked on the extreme rarity of absence of the ulna.

PNEUMATIC PADS IN THE TREATMENT OF UNUNITED FRACTURES OF THE HUMERUS.

Mr. C. MAX PAGE read a paper on Pneumatic Pads and their Application to the Treatment of Ununited Fractures of the Humerus. He pointed out that the principle of applying a slow acting reducing force held an important position in the correction of most deformities. A force of this kind was generally obtained from the elastic recoil of the tissues against some form of fixed splint. When some degree of reduction had been effected by such means an adjustment, or often replacement, of the apparatus became necessary in order to "recharge the recoil spring." It appeared to him that in some cases the use of pneumatic pressure could effectively add to the reducing force and increase its range of action. He had first employed pneumatic pads in 1913 in conjunction with corrective plaster jackets applied after the Abbott method. The air pad replaced the felt packing between the jacket and convexities it was desired to reduce. This application of the pads was certainly effective, and considerably increased the amount of reduction which could be effected by one jacket.

The pads were made from sections of motor inner tubes of a diameter of 2½ to 4½ inches. Convenient lengths varied from 3 to 9 inches. The ends of the section of tubing were vulcanised, and an ordinary bicycle valve was set in at a convenient position. The tube was enclosed in a fabric case of such a size as to limit its undue expansion when inflated. Pads made in this way by a competent tyre mechanic would retain pressure up to 20 or 30 lb. to the square inch, in the same degree as a bicycle tyre. These pads when inflated became cylindrical in form, and so would exert pressure evenly along the line of their axis. Clearly, however, by placing the pads between two plaster casings, ressure could be distributed as required for any special urpose.

He had recently employed these pads in the treatnent of certain ununited fractures of the humerus, the im being to exert a graduated compression at the seat f fracture along the long axis of the bone. He conidered that fractures of this bone often developed the ondition of delayed or non-union on account of overxtension by the weight of the limb or from the absence f any pressure along the long axis of the bone. Pressure of this kind was undoubtedly of value in timulating union in fractures of the tibia or femur, and there seemed to be no reason why the method should not be equally effectual when applied to the upper extremity.

The method of application was shown in the two cases of ununited humerus brought before the society, and was as follows. A plaster case is applied over the shoulder, arm, and forearm of the affected side, usually with the arm rigidly abducted, and with the elbow flexed to a right angle. A small pneumatic pad is placed under the plaster beneath the elbow, which is covered with a felt pad. When the plaster case is hard the pad is inflated to the degree necessary to push the lower fragment upwards in the axis of the bone against the upper fragment, the casing as a whole maintaining the lateral stability of the arm. He had not yet had sufficient experience of the final results to define the limitations of the method, but he thought that it afforded a simple means of applying to the humerus a method of treatment which had long been proved effectual in many cases of delayed union in the tibia.

In reply to a question by Mr. ELMSLIE, Mr. PAGE said that there was no doubt that a sufficient range of movement could be obtained by the inflation of the pad. The extent of this was determined by the diameter of the casing enclosing the tube; this could be varied as required, but was usually 2½ inches.

In reply to a question by Mr. EVANS, he said that he had seen pressure sores produced by the use of the pads employed inside spinal jackets, but not in cases of fracture of the humerus. He considered they could be avoided by reasonable precautions in the use of felt and in avoiding excessive inflation of the tube. It should be remembered that a pad could be inflated so as to exert a pressure of over 30 lb. to the square inch, when it would become as hard and resistant as a bicycle tyre.

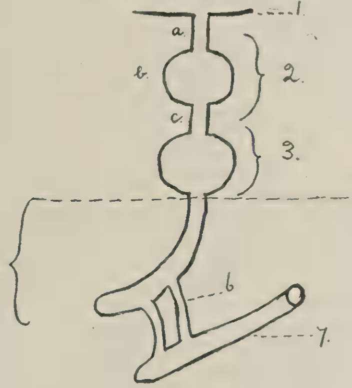
SECTION OF OBSTETRICS AND GYNÆCOLOGY.

ORIGIN OF TUMOURS OF THE OVARY.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 5th, Mr. J. D. MALCOLM, the President, being in the chair.

An abstract of a paper by Dr. JAMES GOODALL on the Origin of Tumours of the Ovary was read by Dr. CUTHBERT LOCKYER, who said that in order to determine the origin of epithelial tumours of the ovary Dr. Goodall had made a study of the embryology of the organ so as to obtain first-hand knowledge of the origin and development of the epithelial structures found therein. A study of comparative embryology was necessary, and his work was based upon sections, both serial and non-serial, from the ovaries of 127 individuals of all ages, including serial sections of five human embryos. The comparative study covered some 15,000 sections from the cow, sheep, cat, mouse, rabbit, guinea-pig, and dog. Dr. Goodall laid great stress upon the importance of working with serial sections, and found that the most serviceable ovaries for study were those of the cow and dog. The close resemblance, from the developmental point of view between the mammalian ovary and testis soon became apparent to him, and he stated that there was nothing in the testicle that had not had at some time in embryonic life its homologue in the ovary. Of the permanent testicular structures, some in the ovary were transitory and disappeared completely, others degenerated but did not disappear, others remained but were modified to suit a modified function. The ovary of one mammal differed from that of another mammal in the amount of atrophy that ensued after the organ had reached its full structural development. The ovary of the cow and that of the bitch suffered the least amount of atrophy. In the ovary of the bitch was found an abundance of epithelial structures. In the medulla and among the great bloodvessels was the rete ovarii, corresponding to the rete testis. According to Dr. Goodall it is an irregular tortuous gland-like structure, with folded mucosa, lined with columnar epithelium. In the human subject it is of variable size and is a fœtal remnant, whose atrophy up to complete disappearance is quite the exception, though, at times, it is so diminutive as easily to be overlooked. Its total disappearance has often been noticed in sheep. Communicating with the rete ovarii are the medullary rays. These are irregular, convoluted, epithelial structures seen either as solid cords or as tubules, which run from the cortex to the centre of the ovary, so that they join up the rete ovarii in the medulla with the surface of the ovary externally or peripherally. They present three types of cell: (1) Shaggy, filamentous cells with basal nuclei; (2) cells syncytioid in shape; (3) cubical or duct epithelium. These types pass almost imperceptibly the one into the other. Dr. Goodall had described the development of the epithelial tissues of the ovary in detail, and their study had led him to the conclusion that there is direct continuity between the surface-epithelium of the ovary and the Wolffian duct through the medium of the medullary cords or tubules, the rete ovarii, and the Wolffian glomeruli, tubules, and duct. (See diagram.)

Diagram showing the Relation of Embryonic Structures to the Adult Ovary.



a, Pflüger's tubules atrophy and disappear. *b*, Becomes the normal Graafian follicle. *c*, Atrophies more or less, may or may not be absorbed. 1, Surface of ovum. 2, Medullary ray. 3, Rete ovarii. 4, Boundary of ovary. 5, Mesosalpinx. 6, Kobelt's tubes. 7, Gartner's duct.

This continuity of epithelial structures is best seen in the embryos of the cow, in which it had been traced as follows: Firstly, the down growth of solid cords (Pflüger's cords); secondly, these cords continued downwards as medullary cords; thirdly, the canalisation of these cords to form the tubules of the medullary rays; fourthly, the continuation of these rays into the medulla as the rete ovarii; fifthly, the continuation of the rete ovarii into the mesosalpinx to join up with the Wolffian tubules and duct. Thus, at a stage in development of the ovary of the cow, the epithelial tubular system is as perfect in its continuity as it is in the testis. Dr. Goodall had pointed out that the parts of this tubular system which occupy the cortex have to do with the generation of the reproductive elements; the remoter portions are the conduits along which ova should travel if they pursued the same course as spermatozoa in the male. But, as ova are cast off into the peritoneal cavity, the efferent tubules become useless and atrophy completely or in parts. It is the atrophy which ensues in the ovary owing to the ova pursuing a different route of migration which has led to so much confusion. A study of the adult organ cannot give any connexion whatsoever between these various parts of one and the same system owing to the complete atrophy of intervening links.

Dr. Goodall had drawn up the following scheme to show the homologous parts of ovary and testis:—

Testis.	Origin.	Ovary.
Seminiferous tubules Vasa recta Rete testis	From germinal epithelium.	Pflüger's tubules. Vasa recta. Rete ovarii.
Efferent canals	From Wolffian body.	Kobelt's tubes of epoöphoron.
Vas deferens	From Wolffian duct.	Gartner's duct.

The development of ova.—Dr. Goodall had found immature ova developing in situ in the medullary rays and even in the rete ovarii, and he regarded this as incontrovertible evidence of the origin of these tubules from the germinal epithelium, and not, as some think, from the epoöphoron. The important function of oögenesis could not be assumed by the epoöphoron; it was essentially an ovarian function. In the lowest mammals oögenesis goes on throughout the whole of sexual life in the bitch, and, as regards the cow, at particular periods. In his opinion the syncytioid cells which form the second type of cell in the medullary rays of the bitch represent the initial stage in the development of ova, while the filamentous cells are the prototype of the zona radiata of the discus proligerus. Most of the immature ova thus deeply developed in the medullary rays and rete testis disappear.

Secondary invasion of cortex by germinal epithelium.—This had been found in the dog and other animals to occur in adult life. It was not thought that this late invasion resulted in the formation of ova. It had never been traced in the human subject, but it offered a ready explanation for that strong tendency in the human ovary for the germinal epithelium, when invaginated, to burrow and give rise to a typical new growth. Interstitial cells arise from the germinal epithelium. This had been proved by Dr. Janet Lane-Claypon and Dr. Jane McIlroy. Dr. Goodall had confirmed their findings.

Origin of Epithelial New Growths of the Ovary.

The second part of Dr. Goodall's paper dealt with the origin of epithelial new growths of the ovary, and in conclusion he discussed the possibility of the origin of perithelioma from the interstitial (epithelial) cells of the ovary. The author first pointed out that the present classifications of ovarian neoplasms was not histogenic, but rather topical, clinical, or histological. This plan had led to wholesale multiplication of varieties, and was to be condemned. He gave the following histogenetic classification: (*a*) Tumours arising from germinal epithelium; (*b*) tumours arising from the stroma; (*c*) tumours due to cell-inclusions. The division of tumours into cystic and solid was, according to Dr. Goodall, unscientific and impracticable. The epithelial structures in the ovary from which tumours might arise were germinal epithelium, follicular epithelium, ova, medullary cords, rete ovarii, corpora lutea, corpora atretica, and interstitial cells. Inclusion-tumours completed the list. The question to ask was whether tumours arose from each of the above. The decision rested upon preponderance of opinion and on personal observation. Excluding hydrops folliculi, Dr. Goodall did not believe that tumours could arise from Graafian follicles either in process of development or during degeneration; he had never seen granulosa cells lining a true cyst. He also thought that hydrops folliculi should not be classed as a tumour or even as a pathological state. Examination of these structures revealed no appreciable change in the ovum or in the membrana granulosa. A Graafian follicle never developed a papilloma. Passing to the consideration of the theca lutein cysts found in connexion with chorionic carcinoma, Dr. Goodall said: "These are true Graafian follicle cysts." The larger ones are devoid of an epithelial lining, since the ovum, being dead, "the membrana granulosa has no longer a raison d'être and slowly liquefies." It was inferred by Dr. Lockyer that the author accepted compound lutein cystoma as a new growth, since he called it "a true cyst." On the question whether the follicular cells of the primordial cell-nests give rise to epithelial tumours, the author stated that such had never been satisfactorily demonstrated, but he regarded this as unimportant, because he proposed to show that "epithelial tumours arise either from this primordial follicular epithelium or from invagination of the germinal epithelium. Small cysts, situated in the immediate neighbourhood of the surface epithelium, may so mimic the epithelium of the primordial follicle that it would be impossible to state, even at the early stage, that it arose from one or the other of these two sources."

The origin of tumours from the germ epithelium.—Dr. Goodall stated that *all* epithelial tumours (except those few which are classified as inclusion-tumours) were derived from this epithelium, either indirectly or directly, through the medium of structures to which it primarily gave rise. He observed: "When we realise that such widely different cells as the apparently simple interstitial cells of the ovary at one end of the list lead through many mutations, through the follicular epithelium, membrana granulosa, ciliated epithelium, mucous cells to the most highly specialised cell—the ovum—we do not cease to wonder at the multiplicity of varieties found among the ovarian grew growths." Dr. Goodall appeared to attribute the origin of epithelial growths to such germ epithelium as was represented by fœtal rests rather than to that which was normal to the mature gland—for example, the Graafian follicle and the primordial cell-nest. He stated that these remnants usually lay deep down in the medulla, often in the region of the rete ovarii, but they might be found in the deep crevices and lobulations of the surface, or again they might be represented by solid columns or real ducts which communicated with the surface. He said: "Other fœtal remnants are to be found in human ovaries of all ages," and that these may be discovered in "a segment which has remained fixed in a stage of imperfect development." Such lack of atrophy of fœtal structures was attributable to a vascular defect which the author regarded as of "common" occurrence, and the portion so influenced looked like a wedge-shaped infarct. It would be found to be "filled with epithelial elements and glands." In such a case the author found multiple cysts and, in one of the larger of these, the wall had become "very vascular and papillary ingrowths quite frequent." The cause of the arrested atrophy of the vascular change, which presumably accounted for it, was a problem, but in one case (a child of 5) the patient had died of chronic nephritis, secondary to scarlet fever, and in another (a girl of 18) the patient had died of a tumour of the brain of syphilitic origin, and the arteries showed obliterative endarteritis. Discussing the influence of perioöphoritis as a cause, the author said that, while it was a fruitful source of cyst-formation, he thought that new growths were not commonly associated with or secondary to inflammatory changes. Such cysts as formed subsided with the subsidence of the inflammation. But if an ovary contained many fœtal remnants perioöphoritis might act as the stimulus that started these into activity.

Tumours arising from ovules: the dermoid and teratomata.—The author stated: "Of late so much has been added to our knowledge ...... that to-day there is but little doubt that the ovules, by a system of parthenogenesis, are responsible for the presence of dermoids and teratomata." Loeb had found that parthenogenesis occurs in about 10 per cent. of guinea-pigs before they are 6 months old. In describing one of these cases Loeb had written: "We see in each case a chorionic vesicle with trophoblast and plasmodia and syncytia penetrating into the neighbouring tissue. There is also a structure present which is probably to be interpreted as the neural tube. As this type of growth occurs in the cortex of the ovary, where follicles are normally seen, and are found within follicle-like cavities, they can be derived only from ova developing parthenogenetically. Fertilisation can be excluded as the life-history of some of these animals is known and precluded such interpretation." Dr. Goodall admitted that, as yet, there is no adequate explanation of extragenital cases. On the question whether pseudo-mucinous cysts arise from teratomata, and therefore from the ova, Landau, Hanan, Ribbert, and Askanazy were quoted by Dr. Goodall as authorities who asserted that a pseudo-mucinous cyst found in association with a teratoma is the expression of the development of the intestinal portion of the teratoma just as the teeth are the expression of its cephalic part. Nevertheless, Dr. Goodall had found mucin mixed with sebaceous material in the contents of teratomatous cysts (dermoids), and this he had shown microscopically to be due "not to a portion of the original wall of the dermoid being a mucous surface," but to the fact that the surface covered with mucous cells had once been a cyst separate and apart and had later been incorporated. However, his conclusion was "pseudo-mucinous cysts are not only ovulogenetic but are also of germ epithelial origin."

The interstitial cells of the ovary.—These cells being regarded by Dr. Goodall as of epithelial origin, he raised the question of tumour formation from this source. He said: "I think the theory quite justified that, inasmuch as peritheliomata occupy morphologically a position midway between carcinomata and sarcomata, its relative frequency in the ovary might readily be explained by assuming that it arises from the interstitial cells which occupy a position morphologically between the epithelial and connective tissue cells."

Discussion.

Commenting on the paper he had just read, Dr. CUTHBERT LOCKYER said that the connexion between the first and second parts of the paper was not obvious at first glance, but the extensive embryological research described in Part I. had apparently been undertaken by Dr. Goodall with a view to classifying ovarian tumours histogenetically. Most people were now agreed that pseudo-mucinous cysts arose from germ epithelium. Any part of the epithelial tract that remains in the adult was excluded by Dr. Goodall from being the origin of tumours, but fœtal rests (*a* to *c* on diagram) alone give rise to new growths. According to Dr. Goodall, all the structures generally regarded as epoöphoron were really oöphoron, and the Wolffian duct exists only outside, and not at all within, the ovary. As to teratomata, the work done by Dr. Herbert Williamson had hitherto been accepted as the last word on this difficult problem. Dr. Goodall's investigations favoured the parthenogenetic theory of their origin, but, while satisfactory enough as an explanation of teratomata arising in the genital organs, this theory in no way accounted for extra-genital teratomata.

Dr. HERBERT WILLIAMSON considered the paper of the very first importance, and congratulated the society on the privilege of hearing the gist of it and Dr. Cuthbert Lockyer on his admirable abstract. Dr. Goodall's paper illustrated the interesting results that could be obtained by extensive research on ovaries of other mammals and their comparison with each other and with man, and also the value of serial sections. He said that the two important points brought out in the paper were, first, the fact that structures formerly regarded as epoöphoron were really oöphoron, and next, the fact that ovarian tubules were not Wolffian but the products of germ epithelium. The Wolffian theory had been dying for some time. It was curious that Keith's work, proving that cysts known as parovarian were really rete-ovarian, was not referred to by Dr. Goodall, as it supported his conclusions. Dr. Williamson had had the privilege of reading the original paper, and had noticed one interesting point not in the abstract; this was a reference to late outgrowths of germinal epithelium in adult life. These outgrowths had been described in 1870 by Waldeyer, who pointed out that they sometimes gave rise to tumours. In another paper Waldeyer stated that he had cut serial sections of 80 ovaries which macroscopically looked normal, but which were taken from patients who had had a cyst removed from the other side. In these ovaries Waldeyer had demonstrated all stages in the formation of a cyst-adenoma, and this observation had been confirmed by the speaker. The deduction as to the origin of pseudo-mucinous cysts appeared to be justified. As to the origin of lutein cells, Goodall regarded them as developed from theca, or interstitial cells, and not from membrana granulosa. On the parthenogenetic explanation of teratomata, Dr. Williamson said that extra-genital teratomata might be due to wandering cells. Dr. Goodall's suggestion as to the origin of peritheliomata from interstitial cells evidently represented an opinion only, as he gave no evidence in support thereof.

Mr. GORDON LEY could not understand the objections to the Wolffian origin of ovarian cysts. An ovary could not be both a downgrowth and at the same time a pedunculated structure.

The PRESIDENT, after a few remarks on dermoids, asked Dr. Lockyer to convey to Dr. Goodall the thanks of the members of the section for the abstract of his valuable paper.

Mr. LEY then read a paper entitled "A Statistical Report of Carcinoma of the Ovary as met with in the Pathological Institute of the London Hospital between the Years 1907–1919 Inclusive, showing the Relative Frequency of Primary and Secondary Ovarian Carcinoma."

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At a meeting of this society, on Jan. 30th, Mr. A. A. Young, Vice-President, in the chair, Mr. Alex. MacLennan, in a communication on "The Repair, by Bone Graft, of Gaps in the Skull due to Congenital Deficiency, Injury, or Operation," said that cases of gunshot wounds of the head were probably best treated by wide removal of bone, a procedure which ensured at once obliteration of the septic region and complete decompression of the brain. Subsequent protection of the area of brain surface thus exposed was best effected by embedding under the scalp an autoplastic bone graft taken from the patient's scapula. Cases and photographs were shown illustrating the successful employment of this method of repair of cranial defects both congenital and resulting from injuries sustained in war.—Mr. John Patrick showed a patient, the whole of whose right hand, except the thumb, had, after being crushed in machinery, been amputated by Lister in Edinburgh in 1870. The thumb had gradually rotated till it now occupied almost a midpalmar position, and resembled rather a finger capable of powerful flexion. The interest of the case was both historical and economic, as the preservation of even the unopposed thumb had enabled the man to follow for the succeeding 50 years his occupation as a letterpress printer. Mr. Patrick also described some surgical conditions observed in the Salonica Army, with which he served as a temporary Colonel, R.A.M.C. The mountainous character of the country on the borders of Macedonia and Serbia had made transport of the wounded a matter of great difficulty, and the average time elapsing between wounding and operation was over 12, and not infrequently as much as 24 hours; hence by the time the patient was operated on sepsis was established and shock advanced. Gas gangrene occurred in a limited number of cases. Surgical conditions arising in connexion with the sickness prevalent in the Salonica Army, chiefly malaria and dysentery, were not many. Transfusion of blood for malarial anæmia was done with good results. Abscesses following intramuscular injections of quinine were common. A series of 35 cases of perinephric abscess were, he said, collected by himself and Colonel H. A. T. Fairbank. In these the symptoms were at first obscure, suggesting the diagnosis of malaria, phthisis, or an infection of the typhoid group. Localising signs were fullness, muscular rigidity, pain, and tenderness in the renal region. X-ray examination showed a vague shadow with obscuring of the psoas lines. Leucocytosis varied from 12,000 to 45,000. Pus was usually present in the urine in small amount. After evacuation of the abscess healing took place rapidly. Staphylococci were always found in the pus, and in some cases a history was obtained of the occurrence of boils prior to the onset of the renal symptoms. Three cases of anaphylaxis, one of them fatal, were described, associated with the prophylactic doses of antitetanic serum administered to every wounded man.—Professor Carl H. Browning discussed some points in the relationship between a positive Wassermann reaction and infectivity in cases of syphilis.—Dr. Taniguchi demonstrated cultures of *Spirochæta icterohæmorrhagiæ*.—Dr. W. Rankin showed a specimen of Papilloma of the Posterior Wall of the Stomach, about the size of a golf ball, removed by transgastric operation, in May, 1919. The patient, a woman, was well and regularly at work in January, 1920, had gained weight, and was able to take any kind of food without discomfort.

Reviews and Notices of Books.

TOTAL DIETARY REGULATION IN THE TREATMENT OF DIABETES.

By FREDERICK M. ALLEN, M.D., EDGAR STILLMAN, M.D., and REGINALD FITZ, M.D. Monographs of the Rockefeller Institute for Medical Research, No. 11. Oct. 15th, 1919. New York: Rockefeller Institute for Medical Research. 1919. Pp. 646.

IN 1913 Dr. F. M. Allen published a review of the literature of glycosuria and diabetes, with an account of numerous animal experiments he had made, and two years later he outlined a plan of treatment by prolonged fasting based upon his laboratory work. Since then he has had the opportunity of putting his methods to the test of clinical experience at the Hospital of the Rockefeller Institute, and, in conjunction with Dr. Stillman and Dr. Fitz, he has now published the results of his observations. At the outset it is emphasised that, although a basic plan of treatment is essential, every case of diabetes must be managed according to its own requirements, and that the best results are obtainable only when the treatment is intelligently individualised. The system followed at the Rockefeller Hospital is based on the principle that diabetes is a disorder of the total metabolism, not of carbohydrate utilisation alone, and that since the trouble is due to a deficiency of the nutritive function, not of nutritive materials, relief may be expected from strengthening this function, even at the price of diminished food-supply and body-weight. This end is attained by causing the patient to abstain from food at first and later by regulating the total diet according to the capacity to assimilate it—that is to say, by systematic under-nutrition. The duration of the initial fast is determined by the results of Benedict's test for sugar in the urine, feeding being resumed the day after the test becomes negative. As the chief danger threatening during the fast is acidosis, careful watch must be kept, and for this purpose the Van Slyke method for estimating the bicarbonate reserve of the blood and the nitro-prusside reaction in the plasma are recommended. The ordinary acidosis of severe diabetes is regarded as no contra-indication to beginning a fast; in fact, the more severe the acidosis the more urgently is fasting demanded, but blind persistence in withholding food may result in some cases in dangerous and even fatal acidosis, and for such patients an under-nutrition diet of either carbohydrate or protein is advised.

It is freely acknowledged that mistakes and errors of judgment have been made in applying the treatment, especially in the earlier cases. The most common mistake was an over-estimation of the patient's tolerance, with a consequently too high level of diet, and a resulting fall in the power of assimilation. In some instances patients had to be readmitted three, four, or five times for readjustment of their diet, and were discharged on each occasion with further restrictions. Such relapses might be taken to point to an inherent progressive tendency in the disease, but it is maintained that there is no real evidence of such a tendency, and the downward progress is regarded as an additional and separate process, independent of the original cause of the diabetes, and arising from the intake of an amount of food beyond the patient's tolerance. It is pointed out that relapse is common in mild cases with a manifest tendency towards recovery, where excessive diets were exhibited which could only be justified on the assumption that a short period of under-nutrition had cured the disease; relapse is rarer in severe cases which, owing to their obvious severity, were kept on low diets for fear of glycosuria and acidosis. Originally it was hoped that if freedom from glycosuria could be maintained for a prolonged period the tolerance would rise, but experience did not justify this hope—any rise appears negligible, at least in severe cases. Full recovery from diabetes is very rare, apparently, and it follows that the method of under-nutrition by which the initial success is gained must be followed in the later treatment if success is to be achieved. Theoretically, exercise might be expected to aid in the attainment of a higher level of diet and strength, but burning up calories by muscular exertion is not fully equivalent to subtracting them from the diet.

In the section on ætiology and pathology the authors lay down the dictum that diabetes is synonymous with pancreatic disease. They claim that clinical diabetes arises regularly on a basis of pancreatitis, either acute or chronic, and that the seat of the specific diabetic disturbance is now firmly established to be in the islands of Langerhans. Although they express the opinion that the pancreas is one of the most frequently diseased organs in the body, so that a strictly normal gland is rather the exception than the rule, they exclude all glycosurias not associated with pancreatic disturbance as non-diabetic, and also assume that a functional incapacity of the cell islets may be responsible for the symptoms. Considerable stress is laid on the diagnostic significance of the hydropic degeneration of the islands of Langerhans, first described by Weichselbaum and Stengl, in spite of the fact that it is acknowledged to be a result, not a cause, of the disease.

This monograph marks an epoch in the study of diabetes. While a cure for the disease has not yet been found, our knowledge is rapidly advancing in regard to the means by which life may be prolonged and the danger from complications avoided. Our thanks are due to Dr. Allen and his fellow-workers for their strenuous attempt to straighten out one of the most baffling problems of medicine, and to the Rockefeller Institute, by whose munificence the work has been rendered possible.

PSYCHOLOGY OF THE NORMAL AND SUBNORMAL.

By HENRY HERBERT GODDARD, A.M., Ph.D. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1919. Pp. 349. 25*s*.

THIS book is written primarily for teachers during or after training and for parents and the general reader. The first three chapters are concerned mainly with the anatomy and physiology of the central nervous system. A ray of light or a sound wave is supposed to stimulate a "sensory dendrite" (p. 19); nervous energy passes under the name of "neurokyme"; the patellar reflex is chosen as an instance of a simple spinal reflex (p. 20); the ascending afferent spinal paths are pictured (Fig. 25) as uncrossed until reaching the bulb; association by contiguity is identified with simultaneous association (pp. 51, 84); the degree of consciousness is supposed to depend on the number of neurons excited (p. 28). "When two stimuli, each arousing a sensation, become firmly associated, the sensations come to have meaning, and this is called perception, or judgment" (p. 180). A child first draws a man as a circular head; "soon he adds eyes, then nose, and mouth, and finally a body. ...... Evidently he puts in these various details as he gets conscious of them, as his neuron patterns develop" (p. 48). If this is the psychology that "must eventually be written from the practical standpoint in terms that can be appreciated by those ...... who do not enjoy symbols to the extent now used in psychological works," we confess to having little faith in it. It appears as crude and as inconsistent as the spellings "thru," "thot," and "brot," which the writer adopts, while retaining such spellings as "plough," "eye," and "one."

The author of this book had a great opportunity before him, but he has missed it. With vast experience among mentally defective adults and children he might have produced a work on general psychology which would have occupied the same position in relation to our knowledge of mental deficiency as, say, Stumpf's "Tonpsychologie" has filled with respect to the physiology and psychology of hearing. This we may suppose to have been originally his aim, for there are various instances recorded of the abnormal behaviour of the feeble-minded, but there is no systematic, sustained effort to build a psychology upon them.

THE ROAD TO EN-DOR.

Being an Account of How Two Prisoners of War at Yozgad in Turkey Won their Way to Freedom. By E. H. JONES, Lieutenant I.A.O.R. With illustrations by C. W. HILL, Lieutenant R.A.F. London: John Lane. 1920. Pp. 351. 8*s*. 6*d*.

THE authors have written an unvarnished, intensely humorous, and absorbing tale of barefaced deceit and trickery and the manner in which they give away their system is creditable, for had they kept their secret they might well have set up in Bond-street as "Apokaluptikos," or some such title, and raked in a large fortune. Lieutenant Jones, however, says in his preface, "If this book saves one widow from lightly trusting the exponents of a creed that is crass and vulgar, and in truth nothing better than a confused materialism, or one bereaved mother from preferring the unwholesome excitement of the séance and the trivial babble of a hired trickster to the healing power of moral and religious reflexion on the truths that give to human life its stability and worth—then the miseries and sufferings through which we passed in our struggle for freedom will indeed have a most ample reward." The book should be read, and read carefully. Every page of it is a record of masterly ingenuity, and a picture of the capability to "stick it" under most adverse circumstances which is characteristic of the higher side of human nature. Especially, Lieutenant Hill's terrible experience in the Gumush Suyu Hospital is a record of endurance which has few parallels. Against the tragedy the rest of the book is comedy of the most delightful description. The working of the "Ouija," the thought-reading exhibition, the treasure hunt, the incident of the "Four Point Receiver," and the totally innocent and unsuspecting manner in which the victims were led on to believe practically anything that Messrs. Jones and Hill wanted them to believe make most appropriate reading for these times of strain and unrest. We in no way wish to give the idea that the book is a mere record of trickery. The trickery was there it is true, but it was all part of a scheme carried out in the most deadly earnest, and only men blessed with an iron will, a gaiety of mind which refused to be beaten down, and extraordinary memories could have carried the scheme through. Accounts of escapes from prison are always fascinating reading, and this book certainly ranks among the most interesting of its kind, to say nothing of the fact that interspersed throughout the narrative are informing sidelights upon the psychology of prison life.

DENTAL CARIES IN RELATION TO ORAL OSMOSIS.

By RAGNAR ECKERMANN. London: Williams and Norgate. 1919. With 26 plates. Pp. 264. 28*s*.

THE author of this book would have us believe that the generally accepted view of the pathology of dental cariës is wrong, and that the true explanation is the one he advances. Dental pathologists hold that caries of the teeth is a chemico-parasitic process—i.e., the inorganic matter of the tooth is dissolved by acids formed from the fermentation of carbohydrate food, and the remaining organic matter is destroyed by micro-organisms. The carious process, in the view of these pathologists, starts on the outer side of the tooth and progresses inwards. The author of this book states the converse. In his opinion there are two stages in the progress of caries. In the primary, plasma from the pulp passes through the dental structures to the outside of the tooth, the passage taken being largely determined by the direction of least resistance. The portion of the tooth invaded by the blood plasma he terms a "carious canal." This portion of the tooth is then liable to be attacked by secondary caries, a process which consists in solution of the inorganic matter, followed by breaking up of the organic matter by micro-organisms. The solution of the inorganic matter is, in his view, due to hydrochloric acid, and the micro-organisms find such food as is necessary to their existence in the blood plasma in the "carious canals."

He supports his theory by destructive criticism and by experiments and observations. His destructive criticism of the chemico-parasitic theory is most unsatisfactory: he does not seem clearly to understand the views of some of the authors he quotes, and he has an unhappy method of distorting their facts to suit his theory. We do not find his experiments conclusive, and we think that his observations are capable of a very different interpretation from that which he gives. We may quote, in justification of this criticism, his observation of that changed band of tissue which runs from the surface of the tooth to the pulp—the appearance is well known to those accustomed to prepare hard sections of carious teeth. It is this band of tissue which he calls the carious canal and which he considers is due to passage of plasma from the pulp. This transition he believes is due to an increased osmotic pressure of the saliva, consequent chiefly upon the use of salt and, to a less degree, of sugar. A far more reasonable explanation of this band of tissue, and one that is in accord with our views of general pathology, is that the changes observed are due to the natural reaction of the tooth to injury from external stimuli.

But the book is certainly interesting, if not convincing, and well worthy of perusal for many of its suggestions.

THE HEALTH OF THE TEACHER.

By Dr. W. E. CHANCELLOR. Chicago: Forbes and Co. 1919. Pp. 307. $1.25.

MOST books on hygiene begin with some account of anatomy and physiology as the basis for understanding the management of health. It is refreshing, therefore, to meet with one showing an entirely novel means of approach: "I seek to distinguish the patterns of life according to the natures of different men," the author, quoting from Plato, declares as his theme. He makes the study of individuality the first step towards promoting health—individuality, the product of physical and racial natures. He indicates the important influence of the ductless glands on the physical side, and on the racial side he identifies predominant characteristics of the nine breeds of individuals (Saxons, Scots, Irish, Dark Picts, and so forth) which are conspicuous among those who adopt the teaching profession in America. Then he proceeds to analyse human nature according to temperament (the ideo-motor, vital-corpulent, &c.). From these foundations he passes on to the study of individual cases, indicating the diseases and weaknesses to which they are likely, through their racial, physical, and temperamental constitutions, to be particularly liable. The second part of his work is primarily of an advisory nature, providing the rationale of health control.

Perhaps, on the whole, the author gives more attention to the woman teacher than to the man, but with both he is conspicuously human in his treatment of his subject, appreciating in their effect on health the circumstances and events of the teacher's daily life. He discusses, for example, questions of home life, daily journey to and from school, periodicity (diurnal, hebdomadal, mensal, annual), recreation, dress, diet, sleep—all in a simple, illuminative, novel, and thoroughly entertaining manner. To marriage as it affects the teacher he devotes considerable attention, upholding the position of the married woman teacher. On every school staff, he holds, there should be some married teachers, not only because their parental experience enables them to manage children sympathetically, but because they are healthier and live longer. Love affairs and courtship, important factors in health and efficiency, he discusses with a frankness not known in the text-books on hygiene in this country.

This book is entertaining, provocative, and so original in its presentation, that while we do not recommend it precisely as a text-book on hygiene, we do advise that it should be read in conjunction with other works on the health of the teacher. Alone, it might tend to induce undue introspection and anxiety, and because some of its dicta are based upon attractive, though as yet unsubstantiated, theories it would fail to provide an absolutely sound scientific foundation to the study of health.

Reports and Analytical Records

FROM

THE LANCET LABORATORY.

MALTO.

(THE PHŒNIX TRADING CO., LTD., LONDON.)

THE description that "malto" is a non-alcoholic beer is accurate according to the results of our analysis. On distillation a distillate was obtained showing a specific gravity of 0·999, which means that, practically speaking, alcohol was absent. Otherwise malto presented the composition of a high-gravity beer, the analysis yielding the following results: Total solids, 8·71 per cent.; mineral matter, 0·08 per cent.; malt sugar, 7·34 per cent.; proteins, 0·17 per cent.; dextrin, 1·12 per cent. There was no evidence of objectionable preservatives present and the samples examined were in sound condition and kept so. The beverage is reminiscent of brown Munich beer and has a similar malty flavour. It is agreeably but not excessively effervescing. To sum up, it possesses the same dietetic value as what is called an "extra" stout, with the important difference that it is alcohol-free. The nutritive value resides chiefly in the rich proportion of maltose and dextrin present.

POWEREX.

(POWEREX, 15, CHARLOTTE-STREET, LONDON, W.)

This is a granular powder having the appearance of dried full-cream milk. Its components include, according to statements which have reached us, glycerophosphates and pure dried cream. Our analysis gave the following results: Moisture, 7·60 per cent.; mineral matter, 8·90 per cent.; proteins, 22·33 per cent.; reducing sugar, 40·00 per cent.; phosphates (P_2O_5), 2·62 per cent. The powder dissolves to the extent of 62 per cent. in cold water. So far the claims as to its composition are borne out by this analysis. It responds quickly to the well-known tests for active enzymes. The rich proportions of fat, protein, and carbohydrate are noteworthy.

(1) DIGALEN GRANULES; AND (2) SCOPOLAMINE PREPARATIONS.

(THE HOFFMANN-LA ROCHE CHEMICAL WORKS, LTD. (BASLE), 7 AND 8, IDOL-LANE, LONDON, E.C. 3.)

(1) We have before referred to the claim that digalen is a standardised solution of digitoxin, a claim which has been well supported by reliability of action in therapeutic experience. For convenience of administration digalen granules have been prepared by an approved process, each containing 1/1000 of a grain of digitoxin (Cloetta). The small dosage so presented enables the physician to keep control over the tolerance of his patient. (2) Scopolamine stable (Roche) is claimed to be a stable solution of a pure salt of lævo-rotatory hyoscine contained in ampoules of 1·1 c.cm., enabling exactly 1 c.cm. to be withdrawn by the syringe. Three strengths are supplied. Omnopon-scopolamine (Roche) is a combination of the total alkaloids of opium and scopolamine, which has been used as an adjunct to inhalation anæsthesia, and particularly in painless childbirth. A choice of three strengths is provided.

A MONTHLY RECORD OF ATMOSPHERIC POLLUTION.

METEOROLOGICAL OFFICE: ADVISORY COMMITTEE ON ATMOSPHERIC POLLUTION: SUMMARY OF REPORTS FOR THE MONTHS ENDING

August 31st, 1919.

Place.	Rainfall in millimetres.	Metric tons of deposit per square kilometre.

There were no returns during the month of August from the following stations: Manchester (Whitworth Street Garden and Roof of College); Newcastle-on-Tyne; and Rochdale. Observations for the first time appear from the well-known Rothamsted Experimental Station, Harpenden, Mr. E. Hannaford Richards, B.Sc., of the Lawes Agricultural Trust, being responsble for the analytical results so far recorded. There were no returns from the following stations during September: London (Wandsworth Common); Manchester; Newcastle-on-Tyne; and Rochdale.

"Tar" includes all matter insoluble in water but soluble in CS_2. "Carbonaceous" includes all combustible matter insoluble in water and in CS_2. "Insoluble ash" includes all earthy matter, fuel, ash, &c. One metric ton per sq. kilometre is equivalent to: (*a*) Approx. 9 lb. per acre; (*b*) 2·56 English tons per sq. mile; (*c*) 1 g. per sq. metre; (*d*) 1/1000 mm. of rainfall. Tr. = Trace.

The personnel of public health authorities concerned in the supervision of these examinations and of the analytical work involved remains the same as published in previous tables. The analyses of the rain and deposit caught in the gauge at the Meteorological Office are made in THE LANCET Laboratory.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 14, 1920.

The Origin of Man.

A SERIES of lectures on the origin of man, delivered by Professor G. ELLIOT SMITH at the Royal Institution, have been briefly reported in these columns. Their great and wide interest does not emerge from such short notices, and it is to be hoped that they will be published in full in some generally available form. The first lecture[1] was devoted primarily to the investigation of the precise nature of the determining factors that started the Primates on the particular line of development which culminated in the emergence of man. Stereoscopic vision by an animal, with hands still sufficiently plastic and unspecialised fully to take advantage of the new powers of experiment which such vision made possible, and a brain equably representing the other senses, thus enabling the animal to profit from such experience, were the fundamental factors that started our remote Eocene ancestors on the path which eventually brought some of their descendants to man's estate. Incidentally the lecture was devoted to the explanation of what evolution meant to the biologist and what world-wide wanderings were involved in the process of the evolution of the order to which man belongs.

The second lecture was concerned with the demolition of the speculations falsely called "evolution" of culture by the ethnologists, who have misunderstood what the biologist means by "evolution" and compared it with "spontaneous generation." A specific illustration was taken—the ancient American designs, in which the Indian elephant and the associated myths play a part—to demonstrate how primeval civilisation, even in the most distant parts of the world, was inspired by developments in the Ancient East, the home of invention, proving that the whole history of man's achievements in this direction was determined by the diffusion of culture throughout the world during the last 50 centuries. The third lecture, a brief abstract of which appears in our columns to-day (see p. 409) was devoted to an inquiry into the motives for and the means whereby small groups of men wandered about the world and planted the germs of civilisation in certain places and not in others. Evidence was adduced to show that if gold is the sheet-anchor of the modern world it also played a momentous part in the development of civilisation centuries before the invention of a gold currency. The process which is familiar to us in California, Ballarat, Coolgardie, Johannesburg, and Klondyke, and in the historical records of the search for the Gold Coast, the American El Dorado, the Mountains of Gold (Altai), the River of Golden Sand, and the Golden Chersonese—all this has been going on for more than 50 centuries. In the great majority of cases the spots throughout the world where the germs of civilisation took root in ancient times were the sites of gold or copper mines or of pearl beds; and the men who planted the higher culture in these localities were the miners or pearl-fishers who were exploiting these forms of wealth. The evidence in substantiation of this most important conclusion, which we owe to Mr. W. J. PERRY, of the University of Manchester, is the coincidence of the geographical distribution of megalithic monuments, practices of mummification, terraced cultivation, sun-worship, and a host of other things with ancient mines and pearl fisheries.

The fundamental problem is to determine why gold was sought so assiduously for centuries before the relatively useless plastic metal had acquired its arbitrary and artificial value as currency. The earliest place where gold is known to have been used is Egypt. Golden models of cowries were used as amulets on girdles and necklaces, as the actual shells are still used in East Africa, Oceania, and elsewhere. The Egyptian hieroglyph for gold is a picture of a girdle of cowries. The shells were used, from Upper Palæolithic times onwards, as symbols of the female pudendum—i.e., as "givers of life," and hence came to acquire the reputation of averters of death or even of the risk of death. Hence they acquired in popular imagination the most potent therapeutic powers, and were sought far and wide as amulets to confer the priceless boons of life insurance, health, fecundity, and a continuance of existence after death. So great was the social, therapeutic, and religious value acquired by cowries (as well as other shells and pearls) that the demand soon exceeded the supply. Then models of the shells were made of clay, stone, or any material that came to hand, such as the plastic yellow metal that was lying about, unused and unappreciated, in the very place between the Red Sea and the Nile where the demand first made itself felt. Gold models of the cowrie appealed to the æsthetic sense, and soon acquired a popularity far exceeding that even of the cowries themselves. In course of time the reputation for life-giving and life-preserving, which originally was associated merely with the "form" of the golden amulets, came to be transferred to the metal itself. It thus acquired the reputation for life-giving, for healing, for corpse-preserving, for averting the risk of death, and for giving "life after death," which at first belonged to the shells only. Thus gold became the most desirable stuff to secure—it appealed to man's deepest instinct of self-preservation—and from about 3500 B.C. onwards man began to ransack the whole world for this elixir of life, and incidentally the gold-miner became the missionary of civilisation, and the harbinger of the strife which greed for gold creates.

Fashion in Therapy.

THE medical profession is no more immune than any other section of the population to the influence of fashion, and this is to be expected, for medicine is not an exact science, while every trial along unexplored paths may lead to fortunate issue. If a path looks promising, as long as medical art cannot provide relief for all the ills that flesh inherits, many will go down it. When a therapeutic measure is employed for a series of years, and then is dropped suddenly, the explanation is that at last, and by common consent, it is recognised that that particular path is leading nowhere. The application of hot oil to the stump after amputation was employed for generations because surgeons had appreciated that heat was the right way in some circumstances to prevent severe septic complications; then AMBROISE PARÉ succeeded in proving, almost against his own opinion, that many patients did much better to whom this heroic treatment had not been applied. As a routine treatment hot oil was dropped, but the value of the cautery in some cases is still acknowledged. Venesection had endured for more than 2000 years as the only, or at least the best, method of dealing with inflammatory processes, until the failure of bleeding in the case of some epidemics became demonstrable, and even then the first idea to occur to the conservative mind was that there had been a change in the constitution of the populace. And so venesection persisted, and within the memory of some of our fathers most hospitals used to have a "cupper," who came daily to carry out the instructions which had been left by the physicians or surgeons; even as late as 1860 some hospital calendars contained the name of the cupper. At last the tide turned, intelligent experience of pneumonia putting an end to the general practice of venesection for inflammatory conditions. PIERRE LOUIS showed statistically, some 80 or 90 years ago, that the results obtained by less heroic methods surpassed those afforded by blood-letting. But the pendulum has swung back too far, and there is little doubt that to-day the therapeutic value of venesection is underestimated; it still has its uses and is too rarely employed. In the use of leeches also there has been a wondrous change of fashion. In 1832 21,000 leeches were used in St. George's Hospital, and in 1882 the number had fallen to 754; and we may be sure that in the 38 years that have elapsed since then the number is still more reduced. In 1832, at St. Bartholomew's Hospital, 97,300 leeches were used, and in 1882 only 1700. But there remain wise physicians who employ this simple and effective method of controlling inflammation.

The popularity of drugs with the members of the medical profession also varies greatly; it is due to the blind following of fashion that the use of drugs fell into disrepute, whence the efforts of learned pharmacologists like the late THOMAS FRASER have begun to rescue it. Sarsaparilla, especially in the form of the compound decoction, at one time had an enormous reputation; no small number of surgeons considered that it was as valuable in the treatment of syphilis as mercury itself. Sarsaparilla is now more appreciated by the customers of the herbalist than by anyone else. Yet the drug cannot be utterly without therapeutic value, even if it was formerly rated too high. Being quite unable to live up to its entire claims, it has lost credit completely, and its neglect may be an error. Arsenic, one of our most valuable pharmaceutical weapons, has been affected strangely by the passage of time, for while its real uses escaped knowledge, its possible uses were grossly exaggerated by repetitionary laudation. It was well known in some of its forms to ancient medicine, and we find it extensively employed in the Middle Ages. In the latter half of the eighteenth century it was in great repute for the treatment of malaria. Early in the nineteenth century it began to be used widely for the treatment of skin diseases, and the idea has been firmly implanted in the public mind that there are two infallible drugs for the treatment of affections of the skin, sulphur externally and arsenic internally. A reaction has long since set in, and the use of arsenic by dermatologists has diminished. In THE LANCET recently we reported a meeting of the Therapeutic Society of Paris in which the claims of arsenic for skin affections were declared to be absolutely without foundation, and this belief is shared by many authorities in this country. But there remain, perhaps, as many who, having had great experience in this department of practice, value the drug highly, and maintain that it is of excellent result if properly given. While the medicinal preparations of arsenic are thus losing hold, the organic arsenic compounds are becoming our routine weapon against syphilis.

The following of fashions is by no means harmful. Indeed, it is the right course to take so long as it is not taken in opposition to conviction, and without heed to the mental reservations that are arising. There is a real risk that in the trial of some new remedy or method the old may be forgotten, and therefore the old should not be too hastily cast aside. "Be not the first by whom the new is tried, nor yet the last to lay the old aside," is good advice in matters medical as in general life. Many will remember the enthusiasm with which vaccines were introduced into practice, when it seemed that before long it would be possible to cure every ill with a series of injections of vaccine. The present position of the use of vaccines is far below what might have been expected from what was said then. That vaccines are of value none can doubt, but their sphere of utility is circumscribed, and only too often a vaccine is prescribed because all other methods have failed. The rush to Berlin at KOCH'S announcement of his preparation of tuberculin cannot be forgotten, nor the disappointment which followed. It is certain that new fashions in medicine will be ever arising, and that the hopes raised by them will in many cases, perhaps in a majority, be disappointed. Still, out of the evil of failures true progress will be made, and we must avoid with care docile adhesion to creeds which our judgment tells us may be outworn.

The Dentist, the Welfare Centre, and the School.

IN his annual report for 1918 as medical officer of health for Wandsworth Dr. P. CALDWELL SMITH gives an interesting summary of that borough's activities in respect of maternity and child welfare. It is not proposed to make reference to the varied work undertaken at the six welfare centres, at the Minor Ailment Department, and through the agency of the health visitors; in the main these are typical of the activities to be found in many of our more vigorous communities. Attention is here specially directed to one item in the scheme of welfare work in Wandsworth—viz., the inclusion of dentistry—in order to illustrate the broader outlook on problems of health now adopted by a constantly growing number of progressive public authorities. Dr. SMITH notes that at one of his centres arrangements had been made with a dental hospital for the treatment of mothers and children sent from the centre. At another, with the coöperation of the London County Council, dental treatment was provided for young children at an inclusive charge of 1s. per child, the fee being reduced to 1*d.* in necessitous cases; it was further proposed to extend the scope of dental treatment to include fillings and extractions, and perhaps at a future date the provision of dentures, for mothers on the register of the centre.

There is real cause for jubilation in the fact that a number of local authorities have already gone far towards a comprehensive scheme of dental supervision for mother and child, while still more are now under weigh and beginning to spread canvas. The provision of dentistry is one of the several activities in which collaboration between the Public Health and the Education Committees of the local authorities concerned is obviously of mutual advantage. The dentist appointed by the two bodies jointly would, as an officer of the Public Health Committee, inspect and give dental advice and treatment to expectant and nursing mothers and to young children up to the age of 5. The work could best be done at, or in close connexion with, welfare centres, and, as the dentist's personality became felt, children would be brought with increasing regularity year after year for dental supervision. With the years would probably come the establishment of a dental workshop, through which the dentist would provide dentures in suitable cases for expectant and nursing mothers and orthodontic appliances for children. By such extension of his sphere of influence the dentist would himself be stimulated into becoming an active missionary for the welfare centre, attracting to it to an increasing extent the class of individual whom the centre should chiefly serve. The advantage to the Education Committee of collaboration would be equally patent. The dentist would continue and extend the work already considerably developed under the ægis of the Board of Education, and in due course would enlarge his sphere beyond the child of the public elementary school to include the adolescent of the secondary and the continuation school. At the same time, his labours for the Education Committee would be lightened to a constantly increasing extent by his previous handiwork for the Public Health Committee at welfare centres. The school dentist would thereby himself lose that sense of futility which oppresses him now, through the knowledge that even when he deals with the child at the beginning of its school career he is already late on the field, and has to put up an unequal fight against dental decay which has entrenched itself during the pre-school years. The work, with its varied types of child, adolescent and adult, with its extension to a greater variety of dental operations than is now afforded by school dentistry, would attract men of good calibre for its own sake, and would lead to more continuous and more contented service.

Annotations.

"Ne quid nimis."

ALCOHOLIC MENINGITIS.

THOUGH signs of chronic meningitis are frequently found post mortem in the bodies of those addicted to alcohol, not until the advent of lumbar puncture was there any clinical evidence of the existence of alcoholic meningitis. Indeed, in this country it is scarcely recognised. At a recent meeting of the Société Médicale des Hôpitaux of Paris Professor Maurice Villaret, M. Fr. Saint-Girons, and M. J. Capoulade reported a case of alcoholic subacute meningitis which is important because of the cogency of the evidence of causation, including the demonstration of alcohol in the cerebro-spinal fluid.

A woman, aged 45 years, a worker in metal, was admitted into the Hotel-Dieu on July 1st, 1919, for severe headache. She was so drowsy that she could not give a history. From her relatives it was ascertained that she was of intemperate habits, but they could not say whether her excesses had recently been greater than usual. Her illness began a fortnight previously by frontal and temporal headache, loss of appetite, and constipation. For several days she was somnolent and replied to questions with difficulty. Her face was congested and without expression, and her eyes were haggard. She lay on her back without the slightest movement and complained only of severe frontal headache. The tendon reflexes were brisk, but the plantar were absent. The pulse was slightly accelerated but regular. In the evening the temperature rose to 102·8° F., and there was a little delirium with incontinence of urine. Meningeal symptoms—slight rigidity of the neck and Kernig's sign—developed. On the 2nd these symptoms increased. The patient became more and more torpid and did not understand questions. The constipation was obstinate and yielded only to enemata, and the tongue was thickly coated. The urine was normal. On the 5th lumbar puncture was performed and yielded slightly cloudy fluid. On the 7th there was retention of urine necessitating catheterisation. The rigidity of the neck, Kernig's sign, the headache. and the delirium persisted. The tendon reflexes were brisk and the pupillary reactions were normal. The temperature did not exceed 100·4°. On the 9th lumbar puncture yielded clear fluid, and on the 10th the patient was much better and gradually regained consciousness. On the 31st she was discharged completely cured. Examination of the cerebro-spinal fluid, removed on the 5th, showed a little floating fibrinous filament. On centrifugalisation it yielded an abundant white deposit which contained numerous cells, of which 87·3 per cent. were polynuclear and 2·7 mononuclear. There were no microbes. The fluid removed on the 9th contained 40 cells per c.mm., of which 65 per cent. were lymphocytes, 30 mononuclear, and 5 polynuclear. Fluid was also taken on the 17th and gave the bichromate reaction for alcohol. The Wassermann reaction was negative, both for the blood and the cerebro-spinal fluid.

It is generally stated that lumbar puncture is negative in acute alcoholism, but a number of cases to the contrary have been recorded. In 1901 Dufour reported the first case. An alcoholic woman presented intellectual troubles and paralyses, and succumbed to marasmus in spite of antisyphilitic treatment. Lumbar puncture showed abundant lymphocytosis and the necropsy chronic meningitis. Here alcoholism did not appear to be the sole factor, as there was a history of eight abortions, and three days before death the pupils were unequal. In 1909 Henri Claude observed in an alcoholic subject, 19 years of age, well-marked meningeal reactions with xanthochromia and massive coagulation of the cerebro-spinal fluid. M. Villaret has found polynucleosis and hyperalbuminosis of the cerebro-spinal fluid in two out of a dozen cases of delirium tremens. M. Saint-Girons, with the late M. E. Mosny, observed in an alcoholic woman of 56 a meningeal syndrome characterised almost exclusively by headache, mental troubles, and accompanied by transient superabundant polynucleosis of the cerebro-spinal fluid. Recovery was rapid and the Wassermann reaction was negative. The authors suggested that this was not an example of meningitis properly so called, as the symptoms were so slight and passing, but of meningeal congestion, which may be a prodromal stage of meningeal hæmorrhage, a frequent lesion in alcoholics.

THE PATHOGENESIS OF DEFICIENCY DISEASE.

THOSE who have followed, in recent issues of THE LANCET, the careful studies on deficiency disease in the Near East from the pens of Dr. A. D. Bigland and Dr. J. I. Enright will turn with interest to an account given by Lieutenant-Colonel R. McCarrison, I.M.S., of further experiments[1] made by him at the Pasteur Institute of Southern India on the pathogenesis of deficiency disease. His previous investigations were discussed by us in THE LANCET of July 12th, 1919. Colonel McCarrison now deals with the question of the influence of dietaries deficient in accessory food factors on the intestine, and also on the influence of a scorbutic diet on the adrenal glands. His present series of researches have led him to the conclusion that dietaries deficient in accessory food factors give rise in pigeons and in guinea-pigs to congestive and atrophic changes in all coats of the intestine, also to lesions of its neuro-muscular mechanism, to impairment of its digestive and assimilative functions, and to failure of its protective resources against infection. The functional perfection of the gastro-intestinal tract is dependent in a considerable measure on the adequate provision of accessory food factors derived from fresh fruit and vegetables. Further, certain gastro-intestinal disorders, such as chronic intestinal stasis, in the human subject may owe their origin to the long-continued subminimal supply of accessory food factors. Although Colonel McCarrison's experiments were made on birds and guinea-pigs, and although he deprecates any great readiness to apply too directly to the human subject the experimental results of intensive "vitaminic" starvation in the above-named animals, nevertheless he regards the changes he describes as applicable in some degree to man. He contends that it is with sustained subminimal provision of the accessory food factors that the physician is mainly concerned in practice, complete "vitaminic" deprivation being relatively rare, while incomplete "vitaminic" deprivation or subminimal supply of these accessory factors is relatively frequent. Food deficiency also prepares the soil for bacterial growth, and the resulting morbid states will vary with the nature of the organisms which may become implanted upon it. If this knowledge does not enable us to account fully for such gastro-intestinal disorders as mucous disease, cœliac disease, and chronic intestinal stasis, it will, in Colonel McCarrison's opinion, at least help us to a better understanding of their genesis. Another series of experiments were made with guinea-pigs respecting the influence of a scorbutic diet on the adrenal glands. It was found that such a diet caused pronounced depreciation of the functional capacity of the adrenal glands, and that this impairment of adrenal function occurred before clinical evidence of scurvy became manifest. All these contributions to the literature of deficiency diseases are well worth careful study.

NURSE ANÆSTHETISTS.

IT was stated in a leading article in THE LANCET of Sept. 27th, 1919, that the nurse anæsthetist is accepted in Switzerland. A Swiss operating surgeon writes to tell us how this has come about. The carrying out of narcosis is, he says, left to the nursing sisters in cantonal and communal hospitals because doctors are not available for the purpose. At the smaller communal hospitals the doctor is, as a rule, single-handed, so that the operator has to rely for assistance as well as for narcosis upon the sisters. But even in the larger cantonal hospitals and clinics, at which a number of doctors are available, narcosis is left to the sisters, and the experience with this arrangement has been good. Our correspondent adds that in Switzerland the question whether doctor or nurse is to be preferred for the carrying out of narcosis cannot be answered with a direct yes or no. The doctor, by reason of his education, has a better understanding of the physiology and pathology of narcosis than the sister, and this is certainly not an indifferent matter. But practice plays a large rôle in the giving of anæsthetics, and in this respect the sisters have the advantage, for few Swiss doctors choose narcosis as their career, while the narcosis sisters in hospitals often give, year in year out, a large proportion of the anæsthetics. While it would be a mistake to hand over narcosis to a doctor simply because he is a doctor, the doctor with constant opportunity to keep in practice is, in our correspondent's opinion, to be preferred to the narcosis sister since his scientific knowledge will enable him the better to foresee and avert the accidents which threaten. In Germany, where probationers give most of the anæsthetics, complicated apparatus is used in the hope of mitigating the dangers which arise from lack of practice, but the practised anæsthetist will get on with the simplest methods. Our correspondent adds that he has never seen better narcosis than that of an English colleague who used "a piece of flannel and a scent bottle." In his own private clinic for many years past a Swiss colleague, a gynæcological specialist, gives ether alone on a Juillard's mask with uniformly successful results. It seems, then, that in Switzerland the doctor anæsthetist is held in proper regard, but that he is rarely available under existing circumstances.

SCIENCE AND INDUSTRY.

THE country under occupation by the Allies in the vicinity of Cologne includes some of the best examples of German chemical industry, and it is interesting to learn that the great factories on the banks of the Rhine have been visited recently by a deputation of British experts. Their report has been issued, and, generally speaking, confirms our previous knowledge of the Germans' activity and their remarkable steadfastness of purpose. It is not so much initiative or ability that they possess as a determination to work out detail and to adapt the lessons of the laboratory to commercial ends. They have turned chemistry to national account, and that is the main lesson of the report to us. In Germany scientific investigation is encouraged, the best advice is gained, and men who are trained to a high level of efficiency are well remunerated. This policy, begun years ago, succeeded, and explains why Germany took a lead over other nations in producing fine and heavy chemicals, pharmaceutical products, and dye-stuffs. The essentials in regard to many processes, naturally enough, are jealously guarded, and presumably it was not the mission of the experts to extract, in many instances, manufacturing secrets. The report is an instructive one, and should have a healthy and stimulating effect on the chemical industries of this country. We are not behind in ability, but we are slow to reap, commercially and nationally, the harvest of our scientific attainments.

AUTOPSIES ON PRISONERS OF WAR.

Professor Rinaldo Pellegrini, of Parma, whose article on simulation in prisoners of war has recently received notice in THE LANCET,[1] describes the results of about 100 autopsies[2] performed by him during his confinement at Celle (Hanover). The excellent water-supply and perfect system of drainage prevented the appearance of the most serious forms of infectious disease. No cases of typhus or cholera occurred. More than a third of the deaths were due to tuberculosis; broncho-pneumonia and lobar pneumonia were fairly frequent, dysentery was rare, there were two cases of malignant growths, two of tuberculous meningitis, and one example of Pott's disease. The œdema of prison camps, though fairly diffuse, was never by itself a cause of death. In almost all the cases, in spite of the youth of the patients, the aortic arch and descending aorta showed patches of arterio-sclerosis, the condition being attributed by Pellegrini to the bodily and mental stress of war and the inanition suffered during imprisonment. Brown colouration of the myocardium, and in more advanced cases brown atrophy, were frequently observed as the result of chronic underfeeding. The same cause accounted for status lymphaticus and the absence of a persistent thymus, which were not infrequently found in autopsies on soldiers at the front. The hilar glands in cases of tuberculosis sometimes showed no specific lesions, this being due principally to the greater facilities for exogenous infection and the more rapid course of pulmonary tuberculosis among prisoners of war. Chiefly as the result of the consumption of war bread, an inferior quality of which was given to the prisoners, gastric catarrh and erosions and chronic enteritis were frequently found.

PHYSIOLOGICAL RESEARCH AT NAPLES.

THE Zoological Station at Naples has long been known to biologists as a place where the worker is free to carry out researches on his chosen subject independently and without let or hindrance, and with the advice and guidance of the expert staff when desired. Work-tables are rented at the rate of 2500 francs per annum (payable in gold) and as, since 1915, the number of tables let to States has greatly diminished the station is now in need of additional support. Professor E. Gley has recently called attention[1] to the section of physiology and physiological chemistry at the same station, the laboratory equipment of which corresponds to modern requirements of research. The term "Zoological Station," strictly correct under the directorship of Dohrn, should indeed be broadened to "Marine Biological Station," now that physiological study occupies a place as important as does morphological. The utility of researches into comparative physiology is receiving increasing recognition. For biological chemistry, for the study of functional activities, of immunology, and of general physiology it is of the highest importance to be able to experiment with organisations so varied, presenting functions so diverse, as those which inhabit the sea; and the richness and variety of the fauna of the Gulf constitute a chief reason for attracting physiologists to Naples, while in Professor F. Bottazzi the section is fortunate in possessing a director of scientific eminence and polyglot facility. There are, it is true, other marine laboratories in Europe, but with the possible exception of Tamaris-sur-Mer (Var) they lack proper provision for physiological study. At Naples the excellent installations stand ready for use, there is a library of more than 30,000 volumes, with abundant sets of periodicals, and the student will have every help and encouragement.

MERCY FOR THE CHILD.

IN Vienna during the first week of the present year 371 children were born alive and 56 dead, while during the same period 735 deaths were registered, 104 of them ascribed to pulmonary tuberculosis. With 2 deaths to 1 birth the problem of surplus population will not take long to solve itself, even in a capital city. Our Vienna Correspondent last week noted that less than 3 per cent. of the 186,000 school children examined were in a state of good nutrition, and expressed his misgiving at what might happen in the event of epidemic outbreak. In Buda-Pest the situation is still more terrifying, since the already starving wartime population has been almost doubled by the influx of fugitives. Miss J. E. Vajkai, the Hungarian Red Cross delegate, writes from Geneva, under date Jan. 28th, that "the little half-naked children find really every possibility to die." If hunger and cold do not bring immediate release tuberculosis is ready to do its slower work. Nor is the situation much different in adjacent countries for the American Relief Fund is providing a daily 600-calorie meal for 1,300,000 children in Poland and for 500,000 little Czecho-Slovaks. In Germany, which has already stepped in to offer relief when Vienna was at its last gasp for bread, rickets has endangered the limbs and prospects of a large proportion of its town children, as Professor Engel showed for Dortmund in our issue of Jan. 24th.

[1] THE LANCET, Dec. 27th, 1919, p. 1201.
[2] Giornale di Medicina Militare, Jan. 1st, 1920.

[1] Revue générale des sciences pures et appliquées.

The ring of neutral neighbours, unable to bear the story of such misery, has long been offering hospitality to relays of starving children, and already some 30,000 Viennese children have been entertained for a month or more in Switzerland, Holland, Denmark, Scandinavia, and recently—to its infinite credit—in Italy. This country has responded by raising a sum of money, now amounting to nearly £100,000 for starving women and children, and at the suggestion of Sir Thomas Cuninghame an infant welfare supply centre is being organised by the Friends' War Victims Relief Committee in each of the 21 wards of Vienna. All these measures touch as yet but the fringe of the need. But this week the Bradford City Council nearly resolved that the Aliens Act should no longer deter Yorkshire, at all events, from showing mercy to the children of its late enemies. A proposal to offer hospitality for 12 months to 1000 children of school age from the famine areas of Central Europe failed by a small minority in the Council, being replaced by a unanimous vote to subscribe largely to the relief fund.

But Bradford's lead may be followed at once by Manchester, which is to provide for 2000 children if that city accepts its Lord Mayor's guidance. It only remains for every town and village in the country to follow suit after its kind. Who does not give quickly may have no chance of giving at all, for the on-coming of severe weather may at any moment render help too late for many of the victims, and much more difficult for the remainder. To introduce a stranger into the home circle may seem to some a venture of faith, but the visit need not be indefinitely prolonged, for we have high authority for believing that the food-supplies of the world can be increased very rapidly,[1] while there are tens of thousands of families with a working margin, it may be small, but just large enough to take a guest. Voluntary rationing is notoriously difficult, but there is little reason to fear that the automatic reduction of the standard of life caused by one additional mouth will have any unpleasant result. On the contrary, the experience may restore to many citizens that sense of championship of high international ideals which took them into the conflict in 1914.

THE LANCET, Jan. 3rd and 10th, 1920.

THE Manager will be obliged to readers who have not any further use for their copies of THE LANCET of the above dates if they will kindly return them to him at 1, Bedford-street, Strand, W.C. 2. The postage on the numbers is one penny each. He will be pleased to pay the full price for copies returned, as he is disposing of them again to new subscribers.

CONTROL OF VENEREAL DISEASE:

THE QUESTION OF PROPHYLAXIS.

Memorandum of the Medical Women's Federation.

IN an eight-page foolscap pamphlet issued by the Medical Women's Federation from 9, Clifford-street, London, W. 1, are contained the considered views of the Federation in the form of "Some Suggestions as to the Duty of the State in the Control of Venereal Disease." The conclusion was unanimously reached by the Committee appointed to draw up the Memorandum, which was subsequently approved at an extraordinary meeting of the Federation, that "the chief and most important part of the task with which society is faced is such a reform of our social structure and of our moral habits as will gradually eliminate from society conditions which have led to the prevalence of venereal disease." In regard to prophylaxis, the Federation associates itself with the findings of the Interdepartmental Committee on Infectious Diseases in Connexion with Demobilisation.[1] The Memorandum proceeds:—

"It is obvious from this Report that even under the conditions of discipline of men on active service during war there was no proportionate reduction in the infection rate of those sections of the forces in which the prophylactic packet system was most thoroughly used. In the British Forces the infection rate remained practically the same throughout the war, though during the latter part of it the packet system was very largely used, while in the Australian Forces, where the system was used probably more thoroughly and with more enthusiasm than in any other section, the infection rate was considerably higher at the end than at the beginning.[2] In certain units of the forces, however, where during the recent war the packet system was used with great zeal and energy, the percentage of venereal disease is said to have been afterwards very markedly diminished.[3] It must be remembered that the zeal and energy of the administration was certainly not confined to this one method of stamping out the disease. Also the very fact of the enthusiasm and activity of the officer in command would communicate itself to the whole unit, who would be stimulated to use precautions against the disease. It would be impossible that such personal influence should make itself felt when the system became part of the general civilian sanitary administration. The civil health authorities could not command and control the general population as can be done in the army. The evidence laid before the Interdepartmental Committee on Infectious Diseases in Connexion with Demobilisation points to the conclusion that though 'certain drugs, if properly applied, are efficacious in preventing venereal disease,' yet it is not possible in the army, and would be still less possible among the civil population, to make certain that the drugs were properly or skilfully applied. The immunity obtained by their use would be quite certainly incomplete. We agree with the Committee in its statement that the issue of prophylactic packets 'tends to give rise to a false sense of security, and thus to encourage the taking of risks which would not be otherwise incurred,' and also that 'under any mechanical system which does not give absolute protection, the venereal incidence must be proportionate to the risks taken,' and we hold that if the introduction of such a system leads to an increase in the number of exposures, as would, we consider be practically certain to be the case, it might very easily absolutely increase the spread of the disease.

Prophylactic measures in women.—"In women either prophylaxis or early preventive treatment would be used as a preventive of conception. The complete carrying out of such a system must include the distribution of packets and the placing of posters drawing attention to the system in public lavatories and other suitable places. Whether or no safety could be obtained, promiscuous intercourse would be looked upon as free from risk of infection, and to a great extent free from risk of conception, and as recognised and protected by the State and health authorities, who would become in the eyes of the ignorant the consenting party to their actions. We believe that by no such method can the problem of venereal disease be met, and that a phase of society would be produced as vicious and degenerate as any of which history has record. Safety from infection would not be attained, while moral degeneration and sex excesses would rot the very foundation of society.

---

[1] Cmd. 322. Prophylaxis against Venereal Disease.
[2] L. W. Harrison: Journ. Roy. San. Inst., 1919, p. 100.
[3] G. A. Reid: Ibid., p. 85.

"We wish to make it quite clear that we are not advocating the retention of disease in order that the fear of infection may deter from promiscuous indulgence. Our point is that promiscuous indulgence would not be safe, while the attitude of the State would encourage the false idea that it was safe and countenanced by the authorities, and so would inevitably lead to increased indulgence and quite possibly to increased disease.

"*Early preventive treatment.*—The provision of early preventive treatment at the public expense at clinics by skilled nurses, male and female, which clinics are to be open at all hours of the day and night, so that sterilisation of the parts may be skilfully carried out within a short time of the act, is also condemned by us, for the same reasons for which we condemn the prophylactic packet system. We protest against the use by the public authorities of any such system, which must lead to the impression that casual intercourse is being made safe and countenanced by the State, and so to the destruction of the sanctions of conduct in sex matters on which our society is based.

"The sale by chemists, to those who wish to purchase them, of calomel ointment or of permanganate of potash solution is a matter with which we have no concern as long as the public is aware that these things are not remedies for venereal disease and that chemists are under a legal obligation not to sell them for the purpose of treatment of these diseases."

The Memorandum concludes with a statement of the constructive policy of the Federation.

The Mansion House Meeting.

A largely attended meeting, convened by the Society for the Prevention of Venereal Disease, was held at the Mansion House on Feb. 5th, the Lord Mayor presiding. Lord Willoughby de Broke, President of the society, moved a resolution to the following effect:—

"It is obvious that the best way of avoiding venereal disease s to abstain from promiscuous sexual intercourse. It is, however, certain that a large number of persons continue, in spite of moral teaching, to expose themselves to risk and so to incur and spread disease amongst the community, the chief sufferers being women and children. Venereal disease has become a menace to national health and prosperity, and n view of the proved fact that infection can be prevented by means of self-disinfection, if properly applied, immediately after exposure to risk, it is necessary to instruct the public as to (*a*) the vital importance of self-disinfection at the time of exposure to risk as a preventive of venereal disease; and (*b*) the methods of application."

Lord Willoughby de Broke contended that the efficacy of early self-disinfection as a preventive of venereal disease had been proved during the war, and he was satisfied that the method could be applied to the civil population. It was, he said, immoral to suppress the truth, and the society over which he presided would not accept the responsibility of concealing from their fellow citizens one of the principal means of stamping out a terrible scourge.

Sir James Crichton-Browne spoke of the grave objections applying to "venereal lavatories," as he termed early treatment centres, where the protection offered came too late to be effective. Such centres would be costly in large towns and impracticable in rural areas. Those attending them would lay themselves open to suspicion and possibly blackmail. The general public should, he said, be informed as to the vital importance of self-disinfection and the means for carrying t out.

Sir E. Ray Lankester said that in order to realise its purpose of diminishing and possibly abolishing the awful damage to life and health due to venereal disease the society intended to spread as widely as possible an effective knowledge of the use of disinfectants for its arrest. They intended to take steps to ensure that it should be an easy matter for anyone to purchase, and to keep in a form ready for immediate use, the two disinfectants approved by authority—namely, permanganate of potash, 5 gr. in half a pint of water, and calomel ointment of the strength of 33 parts by weight of calomel to 67 of a mixture of lanolin and vaseline.

After Sir Arthur Sloggett, Sir G. Archdall Reid, Miss N. March, Dr. A. Mearns Fraser, Miss E. Rout, and Sir W. Arbuthnot Lane had spoken in support of the resolution, it was put to the meeting and carried unanimously.

Directions for Immediate Self-disinfection.

The instructions for immediate self-disinfection, as issued by the Society for the Prevention of Venereal Disease, are as follows in respect of (A) materials required, and (B) methods of application.

A. Materials required.—(*a*) Some cotton-wool. (*b*) A bottle containing a solution of potassium permanganate, 1 in 1000. (Details below.) (*c*) Some 33 per cent. calomel ointment. (Details below.)

B. Methods of application.—I. If exposure to risk takes place out of doors or where complete disinfection is impracticable: (1) Make water. (2) Soak a swab of cotton-wool with the solution of potassium permanganate. Draw back the foreskin, carefully swab the head of the penis and the under surface of the foreskin, especially at the opening of the pipe. These steps must be taken within an hour of exposure to risk. (3) On returning home the sexual organs must be thoroughly washed with soap and water, and 33 per cent. calomel ointment well rubbed into the penis, drawing back the foreskin as in (2) above. This must be done within six hours of exposure to risk.

II. If exposure to risk has taken place indoors, a more complete immediate disinfection should be made: (1) Make water; (2) wash the sexual organs and parts round with soap and water; (3) swab with potassium permanganate solution as in "I"; (4) rub calomel ointment well into the penis.

Note I.—The *careful* swabbing of the penis with the solution of potassium permanganate is the *most important* measure.

Note II.—It is an excellent additional safeguard to apply the calomel ointment *before* intercourse.

III. If exposure to risk has occurred whilst under the influence of alcohol so that the precautions recommended in "I." and "II." have not been promptly taken, the chance of infection may be considerably lessened, though it cannot be removed, by taking as soon as possible all the steps mentioned in "II.," well rubbing the ointment in for ten minutes, and in addition syringing the pipe with potassium or permanganate solution of half the strength recommended for sponging the outside; that is, add an equal quantity of water to the solution, and squirt about a teaspoonful up the pipe with a *small* glass syringe. Do this three times, and then fill the pipe and hold the solution in for two minutes by pinching the lips of the pipe. This method is not nearly as reliable as the *immediate* disinfection, and is useless after 12 hours.

IV. If none of the above precautions have been taken, and there is reason to believe that infection is probable, a doctor should be consulted at the earliest possible opportunity.

Note.—The above methods of self disinfection are only useful for *preventing* the diseases and are *quite useless for cure or treatment* if the diseases have already started.

V. *Prescriptions for materials required.*—(*a*) Potassium permanganate solution: dissolve one five-grain tablet of potassium permanganate in half a pint of water. Four tablespoonfuls of this solution in a small bottle will be enough for one application. (*b*) Calomel ointment (special strength): Calomel 3 parts, lanolin (hydrous) 4 parts, white vaseline 2 parts. Half a small teaspoonful will be plenty for one application.

Education of the Public.

The address given by Sir W. Arbuthnot Lane at the meeting at the Central Hall, Westminster, on Dec. 16th last appears in full in the February issue of *Public Health.* Sir W. A. Lane states that the object of the Society for the Prevention of Venereal Disease is based upon the principle of spreading the truth, the whole truth, and nothing but the truth about venereal diseases, their causation, prevention, effects, and treatment—in other words, "we must educate the public." He goes on to say:—

"It is obvious that in the vast majority of cases chastity is the only way by which venereal diseases can be avoided; yet we recognise that the nature of mankind is such that irregular intercourse will continue to take place in the future, as it has done in the past, and that means must be adopted to reduce infection to a minimum in order that the community shall suffer as little as possible and that these diseases shall be eliminated from amongst us. To attempt to terrorise men and women by depicting the results of these diseases in exaggerated terms is futile, and will have as little effect on them as the fear of an imaginary hell exerts upon an educated people. Should men be impelled to indulge a natural healthy appetite, which varies widely in intensity in different people, such persons should know the most effectual means of avoiding infection and how and when these means should be employed to the best advantage. They should be in possession of the necessary equipment of drugs in a convenient form, so that they may be employed as soon as possible after intercourse.

"The society," he concludes, "hopes soon to have sufficient means at its disposal to spread the knowledge of the preventive measures against these maladies among the members of the lay public, and to reduce and finally exterminate venereal disease."

The Alliance of Honour Campaign.

At a public luncheon given on Feb. 3rd in connexion with the Alliance of Honour the Dean of Lincoln declared that to the wrong administration of the War Office was due much of the evil to be found among the young men who had served in the army. There was nothing in the King's Regulations placing any obligation upon a commanding officer to put down immorality in his command. The time had, he said, come when this state of affairs should be changed, and the Prime Minister was shortly to be approached upon the subject.

TUBERCULOSIS.

Local Hostility to New Sanatoriums.

THE generous offer of a large country house in the Newcastle area for the treatment and training of disabled ex-Service men has recently fallen through on account of local opposition to the men as neighbours. The objections raised by local residents, whenever the establishment of a sanatorium in their neighbourhood is mooted, are so inevitable and have become so stereotyped that their selfishness is apt to be overlooked. Signatures are quickly compiled, "expert" evidence is mobilised, all the arts of obstruction are practised, and a formidable case is presented against the sanatorium, the establishment of which is already hampered by almost countless obstacles. As recently as last November a case of organised local protest against the establishment of a sanatorium was dealt with by a public inquiry, and the evidence against the sanatorium was so standardised, if we may use such a term, and also so illuminated by unconscious humour, that it deserves special notice. The inquiry was conducted by a medical inspector on behalf of the Ministry of Health. On the one side the local council applied for sanction to its purchase of a fine old country house, much used at one time by James I. when hunting in Epping Forest, for the purpose of converting it into an institution for the treatment of tuberculosis. The opposition on the other side was represented by various local interests. The evidence in favour of the establishment of a sanatorium included the statement, from a professor of hygiene in the University of London, who had visited the estate on the previous day, that it was "ideal for the purpose." A characteristic feature of the evidence given on behalf of the protesting residents was the anxiety betrayed lest their district should offer a good enough climate and subsoil for the prospective patients. The estate, it was argued, was in the fog area, both soil and subsoil were unsuitable, and there were no opportunities for expansion at a later date should this be found desirable. Even the dew that waters the area was referred to as being too heavy for consumptives. In fact, a most lugubrious picture was drawn of the local climate, and the anxiety of its residents to save the consumptive from its evil effects was pathetic. We confess that this spirit flourishes to a certain extent on our own lack of exact knowledge concerning the infectiousness of tuberculosis and other problems connected with this disease. Till problems such as those of the subsoil in relation to tuberculosis are solved local residents, medical or lay, and "experts" of any denomination, would do well to refrain from dogmatising.

Krysolgan in Tuberculosis.

Krysolgan is a chemo-therapeutical preparation of gold, introduced in Germany some three and a half years ago. Feldt[1] discusses its present position, remarking that any remedy for tuberculosis must pass two tests: first, it must give rise to focal reaction after intravenous injection, and secondly, such focal reaction must be followed by reparative changes. After these, any variations or intermissions in its action are to be studied. The production of focal reaction seems to have been realised, having been observed in external tuberculous ulcerations. Schnaudigel in a long series of ophthalmic patients reported that krysolgan acted in this respect much like tuberculin, the reaction being either the ordinary inflammatory one, or more frequently "pallor phenomenon." He described a large proportion of cures. Another ophthalmologist wrote similarly, and scientific opinions were, on the whole, favourable; indeed, the diagnostic use of krysolgan was proposed. Bandelier and Roepke used the remedy, especially for laryngeal cases. Combined use is suggested with other agents, e.g., the iodine preparation "alival," and especially tuberculin, the gold preparation being given a day after the tuberculin, when the focus of disease had thus been rendered hyperæmic. Moreover, observation showed that a focal reaction caused by tuberculin could be controlled by a dose of krysolgan, both focal and constitutional signs being mitigated. In this way large doses of tuberculin could be used with impunity. In pyrexial cases Schröder is at present trying small doses of tuberculin, beginning, say, with a thousandth of a milligramme, and simultaneously—that is, on the same days—small doses of krysolgan, from 0·025 g. to 0·5 g. Rapid reduction of the temperature to normal is claimed even in obstinate cases. In all varieties of tuberculosis, however, refractory cases are met with where krysolgan seems without effect. These "gold-refractory" patients, it is suggested, require other specific means in addition: a tuberculin course, or the injection of metallic catalysts, or possibly very small doses of mercury. The author regrets the present scarcity of both of these remedies.

The Work of an Urban Dispensary.

The annual report of the tuberculosis officer for Newcastle-on-Tyne for 1918 shows a decrease in the number of deaths from tuberculosis, most noticeable in the case of non-pulmonary tuberculosis, the death-rate from which was equal to the lowest on record in the city. Investigations into the duration of fatal pulmonary tuberculosis showed that the average was 29 months. The average period between notification and death was 13·6 months. In other words, each patient who died during the year must, on the average, have been ill for 15·4 months before notification. No fewer than 50 per cent. of persons dying from pulmonary tuberculosis had either not been notified before death (18·5 per cent.) or they had died within three months of notification (31·5 per cent.). With regard to family history it was found that among 320 fatal cases there were 132, or 41·25 per cent., with a history of pulmonary tuberculosis in a near relative. The interesting observation was also made that, of those who died of pulmonary tuberculosis, the individuals with a history of phthisical parentage died at a considerably earlier age than others without this history. Evidence of the growing usefulness of the dispensary is found in the increasing number of attendances, the figures being 11,517 as compared with 9286 in 1917 and 7758 in 1916. The work of the dispensary nurses is also reviewed, and the fact noted that when tubercle bacilli have been found in the sputum the patient is visited at least once a month with a view to medical instructions being carried out, and spread of infection to other members of the family being prevented. Of the 1080 sputums examined at the dispensary only 233 were found to contain tubercle bacilli.

A Sanatorium for Merchant Seamen.

At a recent meeting of the Court of Governors of the Seamen's Hospital Society the Committee reported that in connexion with the new hospital for tropical diseases at Endsleigh-gardens, N.W., an effort was being made to establish a sanatorium for seamen on the Hampshire Downs. The percentage of cases of tuberculosis occurring among seamen is not unduly high, but the circumstances of the sailor's calling render it difficult for him to await his turn on the long list of those seeking admission. In the meantime he is tempted to put to sea again with the disease still active, when the conditions on board tend to aggravate the disease and to make him a source of danger to his shipmates. An initial grant has been allocated by King George's Fund towards the purchase of Bramshott Place, Hants, approved for the purpose by the Ministry of Health. A sum of £70,000 is needed for the establishment of the sanatorium, of which the P. & O. Company and its associates have promised £10,000 and Messrs. Furness, Withy and Co. £2500. The office of the fund is at 122, Leadenhall-street, London, E.C. 3.

---

[1] Internationales Centralblatt für die gesamte Tuberkulose-Forschung, Nov. 30th, 1919.

Influenza in Tuberculous Patients.

The outstanding feature of the November number of the *American Review of Tuberculosis* is a paper by Professor Maurice Fishberg on influenza and tuberculosis. He writes: "I have not met a single case of phthisis during the past year which could be ascribed to have followed influenza." After a careful review of his own and others' experience, he maintains that epidemic influenza bears no ætiological relationship to tuberculosis, and that dormant tuberculous lesions are not stirred into activity by influenza. This disease does not run a more acute, severe, or fatal course in the subjects of tuberculosis than in healthy persons, and, as vital statistics and sanatorium reports show, the mortality from tuberculosis has not increased during the past year, although influenza has been raging. He adds: "The pulmonary sequelæ remaining after influenza are almost without exception non-tuberculous in character, and do not require the treatment accorded to phthisical patients."

The *Paris Médical* for Jan. 3rd is devoted to a series of papers on tuberculosis, including a retrospect and a forecast by Dr. P. Lereboullet and Dr. L. Petit. In a review of the relation of influenza to tuberculosis, Dr. M. P. Ameuille comes to the conclusion that, in the course of the last epidemic, influenza rarely attacked the tuberculous, and when they contracted influenza this disease ran a peculiarly mild course. The opinions he expresses as to the effect of influenza on the further course of tuberculosis are guarded. A paper by Dr. C. Sabourin deals with menstruation in relation to tuberculosis.

The *Zeitschrift für Tuberkulose* for December, 1919, contains a paper by Dr. E. Dorn, whose findings with regard to the relation of influenza to tuberculosis are n close accord with Professor Fishberg's. The writer found that among 184 tuberculous patients at the Wilhelmsheim Sanatorium, 111, or 60 per cent., contracted influenza, but only in 5, or 4·5 per cent., was the pulmonary disease temporarily or permanently aggravated. Another curious observation was the reaction of the sanatorium patients to different waves of the epidemic. In the summer of 1918 more than half the patients contracted influenza. The second wave, which swept over the neighbourhood in the autumn and winter of 1918, did not affect a single patient, although the virulence of the influenza was great, and the opportunities for infection by visitors were numerous. The writer admits that the processes by which this evident immunity was acquired are obscure.

AID-POSTS FOR EPIDEMICS IN DURHAM.—The county medical officer for Durham has issued a memorandum, in anticipation of the possibility of another epidemic of influenza, urging the appointment of more district nurses and the organisation of emergency home helps. In order to obviate the difficulty of getting into touch with cases needing assistance he suggests the formation of emergency committees, and the establishment of aid-posts at convenient centres, as in Sunday-school rooms, council offices, and welfare centres. The emergency committee could meet at the centre to discuss the position from day to day if necessary. A responsible person should attend twice daily o take messages left by doctors and others requiring help, and to deal with the cases on the best lines possible. Stores of nursing requisites should be kept at the aid-posts, such as bed-pans, mackintoshes, feeding cups, pneumonia ackets, dried milk, Benger's food, and other invalid material. Voluntary workers would be of great assistance at these aid-posts in dealing with the stores and food. He suggests, urther, that it would be a good plan to keep a reserve of nursing requisites at isolation and union hospitals for use in epidemics.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Postal Services in Dublin: Medical Practice Embarrassed.

THE telephone service in Dublin has been thoroughly unsatisfactory, and is probably worse than in any city of importance in the kingdom. Steps have now been taken to reduce the postal service to the same level. Prior to the war we had a good postal service, but naturally during war-time medical practitioners had to put up with many inconveniences. They, however, were trivial compared with what has to be suffered under the new arrangements. Almost all night work is to cease at the post offices. Two consequences of pressing importance to medical men result. One is that they cannot get their morning letters before the hour at which they usually begin their morning round. The other is that by the time they have finished their day's correspondence the last collection for the night has been made. A medical man is therefore forced to make his appointments two days at least ahead, and if he finds it necessary to alter an appointment he can only do so by telegraph. As an example of the new system, suppose a patient in Dublin writes to a medical man on Monday asking for an early appointment. The letter will be delivered some time on Tuesday. The doctor sends his reply on Tuesday evening, and it will reach his patient on Wednesday afternoon. The earliest appointment cannot be before Thursday. The cross-Channel service is equally bad. The postal authorities now demand an interval of 12 hours in the case of the day mail and three in the case of the night mail between the posting of a letter and its despatch from Dublin. Business must suffer, but medical men feel that lives will be lost.

Hospital Strike at Carrickmacross.

The nurses of Carrickmacross Fever and General Hospital in co. Monaghan have struck work for a minimum salary of £52 per annum, with subsistence allowance of £76. It is said that the patients are without nursing attendance, and that one admitted since has died, though this may in no way be connected with the strike. Appeals to other hospitals have brought no response up to the present—or so I am informed—a circumstance that may be due simply to the scarcity of nurses. Railway men, miners, and dockers, when on strike, get more sympathetic treatment from the press than nurses or doctors.

Coleraine Cottage Hospital.

At the annual meeting of Coleraine Cottage Hospital held on Feb. 6th it was reported that the work of the institution was steadily increasing, there being in 1919 as many as 261 in-patients and 179 out-patients. Financially, the income exceeded the expenditure during 1919 by £11 19*s.* 9*d.* The Coleraine War Memorial Committee has now £1700 in hand, and the chairman, at the annual meeting of the cottage hospital, suggested that it might be handed over as the nucleus of a fund for the erection of a war memorial hospital for Coleraine.

Epidemic Disease in Belfast.

It is satisfactory to know that scarlet fever and measles are quietly subsiding. As the old pathologists used to explain, the virus has "fermented itself out," but notification, isolation, and disinfection have not had a triumph in stopping the epidemics in Belfast.

Ulster Medical Society.

At a recent meeting of this society the following resolution, proposed by Professor J. A. Lindsay and seconded by Dr. J. McCaw, was passed unanimously:—

> "That in the opinion of the Fellows and Members of the Ulster Medical Society it is essential that a clinical examination in ophthalmology, conducted by ophthalmic surgeons, be part of the final qualifying examination for medical degrees and diplomas as heretofore in all Ireland. This seems absolutely necessary if ophthalmology is to retain the position its importance entitles it to in the education of the future medical profession of this country."

Feb. 10th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

A Night Medical Service in Paris.

M. Roux, Prefect of Police, has just issued an order concerning the reorganisation of the medical service in Paris at night. There is to be a service of 30 doctors appointed by the Prefect. The duration of their appointment will be three years at the most, with fixed annual pay of 3000 francs, and the sum of 50 francs for each night of actual work to the five medical men detailed as substitutes. Paris is divided into five sections, in each of which a doctor is permanently on duty from 10 P.M. till 7 A.M. from Oct. 1st to March 31st, and from 10 P.M. to 6 A.M. from April 1st to Sept. 30th. The site of his activities is to be a central police station, where a room containing a bed will be available. The call for the doctor will be made to the nearest police station by the patient; thence a telephone message will be sent to the chief of the municipal police, who will send a motor-car to take the doctor to the patient and then on to the medical station. Each car is furnished with a case containing urgent first-aid appliances, such as dressings, cachets, ampoules, and a small collection of syringes and sterilised instruments. The medical service is so organised that the turn of each doctor comes round once in six days. The labour cases will be catered for by the midwives attached to the night medical service, and the tariff for their visits is fixed as follows: simple visit, 15 francs; simple labour, 35 francs; twins, 60 francs. If a midwife has to resort to a doctor for help she will be able to requisition his services on the lines indicated above.

Overcrowding in Maternity Hospitals.

The rise in the number of births, from an average of 167 a day in December to 203 a day in the first fortnight of January, has occasioned much overcrowding in the maternity hospitals. The fact is aggravated by an evident desire for economy on the part of certain members of the population. One distressing consequence of the situation must unfortunately be chronicled; puerperal fever has recently appeared at several places, and its incidence must be attributed to overcrowding, inadequate equipment, and lack of stores. The only way likely to be efficacious at the moment to prevent its extension is to supply such help to lying-in women as will enable them to remain in their own homes. M. Autrand, Prefect of the Seine, has formed this opinion, and after consultation with the Directeur de l'Assistance Publique he has under consideration the allocation of a new bounty of 50 fr., which would be additional to the sum usually given. Moreover, the regular fee paid to midwives for conducting a labour at the patient's home would be raised from 50 to 70 fr.

Excess Profits Tax Applied to Medical Men.

The Treasury has declared its intention of enforcing on medical men the war profits tax paid by business men and manufacturers on profits made since 1914 in excess of the average of the five years preceding the war. At Marseilles, in spite of protests, the tax has already been imposed. Paris doctors protested in advance, but a test case has resulted in the decision that medical men are subject to the excess war profits tax.

Legacies for Successful Research.

Under the will of Me. Audiffred a prize of 24,000 fr. was offered for the discovery within 25 years from April 2nd, 1896, of a curative or preventive medicine against tuberculosis which should be absolutely certain. The Academy of Medicine has not hitherto felt sure that anything fulfils these conditions. The interest on the capital has not been distributed, though this could have been done, doubtless because it is too small at 3 per cent. to be of much use. If the prize is not won by April 2nd, 1921, the sum of 24,000 fr. and the accumulated interest thereon will become the property of the Academy. The present intention is to found a new prize with the same object, but this time to distribute the interest in annual grants to research workers in accordance with the scheme of the Academy of Science for the Breant prize for research into Asiatic cholera. The interest will be larger because the Academy, having become the owners of 50,000 fr. through accumulation of interest, will sell the present securities and will be able to get 6 per cent. for their money. This will mean 3000 fr. for distribution every year.

Encephalitis Lethargica.

Cases of encephalitis lethargica are apparently becoming more numerous and the area of distribution of the disease is growing larger. Cases are reported from Versailles, Lille, Toulouse, Châlons-sur-Lâone, Vienna, and Mulhouse. M. Remlinger has reported cases occurring in Algiers and Tunis. They appear to be characterised mainly by the long duration of the period of somnolence. The mortality is everywhere about 25 to 30 per cent.

Feb. 9th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Effect of Housing and Sanitary Conditions on Maternity and Child Welfare in India.

A CORRESPONDENT of the *Pioneer* makes some pertinent remarks on this subject. On all sides schemes are being promoted to improve the condition of Indian mothers and to provide skilled attendance at childbirth. But their antenatal conditions cannot be ameliorated until the housing conditions have been improved. Improvement is not likely to be rapid, since the housing of menial classes, even of those employed by Government mills, railways, &c., under European or educated supervision, is still very bad. The employees are lodged in rooms 10 ft. by 10 ft., and more often than not built back-to-back to save a party wall. The usual type of house has in front a useless 5 ft. verandah and a zenana courtyard surrounded by a 7 ft. wall, in which is also housed the family's latrine. This arrangement effectively prevents the entrance of light and air into these cells, the condition of which, with neither light nor through ventilation, is anything but conducive to general health of a family. Improvement of antenatal conditions for an expectant mother is thus impossible. It is useless under these conditions of housing to talk of inculcating domestic sanitation and hygiene; nor, considering the dirty earthen floors and the cells used as living rooms, can infantile mortality be reduced from the appalling figure at present prevailing among the poorer Indian classes.

Bacteriology in India.

From the annual report of the Bacteriology Laboratory, Muktesar, we learn that the total receipts from the sale of the laboratory products amount to Rs. 3,42,402–11–0, and that the expenditure has been Rs. 4,37,712–13–4. The receipts include arrears of the previous year, and bills amounting to Rs. 67,890–1–3 still waiting payment have to be carried over to next year's account. Had not the vaccines and serums supplied to the military authorities been free of charge Rs. 1,38,330–2–9 would now have been available towards their production on a large scale. The result should be greatly to reduce the menace of cholera to troops on service, and we may wonder why this method was not put into practice in the recent operations on the frontier.

An All-India Chemical Service.

A Committee has been appointed to deal with the question of an All-India Chemical Service. Details are now available which show that, unsatisfactory as is the existing position from the point of view of the employer, it is even less satisfactory from that of the employee. The inability of local governments to judge the scientific officers which they employ, or to replace them when they leave or fall ill, has been pointed out. The small but not unimportant results achieved, with the help of the Indian Munitions Board, in marshalling the scientific forces of the country threw into contrast the vast field of possibilities in which no consistent policy is veloping economic assets. However, certain more or s successful attempts have been made from time time to build up an organisation of officers for entific work. Instances such as the Geological rvey of India and the Indian Agricultural Service, ove by their success the advantages of their stems, though the systems of these two departments fer radically from one another. The importance of ganising scientific workers is now widely recognised, l the question for consideration of the Government of lia is the form of organisation best suited to Indian nditions. A scheme for All-India services as a basis of entific organisation has been put forward by the lian Industrial Committee. The Government of lia have decided to deal in the first place with the se of officers employed under Government as chemists, l have, with the concurrence of the Secretary of ate, appointed a Committee with the following terms reference :—

. To consider whether an All-India Chemical Service is best and most suitable method of overcoming the iculties and deficiencies pointed out by the Indian lustrial Commission.

. In the event of the Committee approving the principle [illegible] All-India Service, to devise terms of recruitment, ployment, organisation, to indicate the extent to which mists already in Government employ should be included that service, and to suggest what should be the relations the proposed organisation with the public and with partments of the Government of India and of local vernments.

. In particular to frame proposals for the location, scope, l organisation of institutions for chemical research.

Professor J. F. Thorpe, professor of organic chemistry the Impérial College of Science and Technology, ndon, has been appointed President, and Dr. J. L. nonsen, F.I.C., forest chemist, Dehra Dun, has been pointed secretary of the Committee.

URBAN VITAL STATISTICS.

(Week ended Feb. 7th, 1920.)

nglish and Welsh Towns.—In the 96 English and Welsh wns, with [illegible] aggregate civil population estimated at 500,000 persons, the annual rate of mortality, which had n 15·6, 15·3, and 15·9 in the three preceding weeks, was in 15·9 per 1000. In London, with a population slightly eeding 4,000,000 persons, the annual death-rate was 17·2, 0·4 per 1000 above that recorded in the previous week, ile among the remaining towns the rates ranged from in Rotherham, 7·6 in Gloucester, and 8·1 in Swindon, 22·1 in Liverpool, 22·6 in Grimsby, and 25·2 in eat Yarmouth. The principal epidemic diseases caused deaths, which corresponded to an annual rate of per 1000, and comprised 97 from diphtheria, 96 m whooping-cough, 90 from measles, 63 from infantile rrhœa, 34 from scarlet fever, and 3 from enteric er. Measles caused a death-rate of 2·3 in Grimsby; ooping-cough of 1·3 in West Ham, 1·4 in Leyton, 1·6 in msby and in Birkenhead, and 1·7 in West Hartlepool; l diphtheria of 2·5 in Hornsey. The 98 deaths from uenza were 32 in excess of the number in the previous ek, and included 20 in London, 11 in Leeds, 10 in Liverpool, n Birmingham, and 4 each in Manchester, Bradford, and effield. There were 2487 cases of scarlet fever and 2014 diphtheria under treatment in the Metropolitan Asylums spitals and the London Fever Hospital, against 2550 and 8 respectively at the end of the previous week. The causes 39 deaths in the 96 towns were uncertified, of which were registered in Birmingham, 4 in London, and 3 in nderland.

cotch Towns.—In the 16 largest Scotch towns, with an regate population estimated at 2,400,000 persons, the nual rate of mortality, which had been 16·1, 15·3, and 15·9 the three preceding weeks, fell to 14·7 per 1000. The deaths in Glasgow corresponded to an annual rate of per 1000, and included 6 each from diphtheria and antile diarrhœa, 3 from scarlet fever, 2 from whooping-gh, and 1 from measles. The 83 deaths in Edinburgh re equal to [illegible] rate of 12·7 per 1000, and included 2 from htheria, and 1 each from scarlet fever and infantile rrhœa.

rish Towns.—The 153 deaths in Dublin corresponded to an nual rate of 19·2, or 3·4 per 1000 above that recorded in previous week, and included 5 from whooping-cough, rom infantile diarrhœa, 2 from diphtheria, and 1 from asles. The 146 deaths in Belfast were equal to a rate .8·4 per 1000, and included 12 from measles, 6 from scarlet er, and 2 each from enteric fever, whooping-cough, htheria, and infantile diarrhœa.

The Services.

THE HONOURS LIST.

THE following awards to medical officers, for valuable services rendered in connexion with military operations in North or South Russia or in Persia are announced :—

C.M.G.—Capt. (acting Lt.-Col.) D. C. L. Fitzwilliams, R.A.M.C. (T.F.).

C.B.E.—Temp. Capt. (acting Maj.) E. S. Marshall, M.C., late R.A.M.C.; Col. G. St. C. Thom, C.B., C.M.G., late R.A.M.C.; Lt.-Col. (temp. Col.) C. H. Bowle-Evans, C.M.G., I.M.S.

O.B.E.—Maj. (acting Lt.-Col.) A. W. A. Irwin, R.A.M.C.; Maj. (acting Lt.-Col.) J. M. B. Rahilly, R.A.M.C.; Capt. (acting Lt.-Col.) T. H. Richmond, R.A.M.C. (T.F.); Capt. (acting Maj.) C. G. G. Keane, R.A.M.C.; Temp. Capt. (acting Maj.) A. H. Macklin, R.A.M.C.; Capt. (acting Lt.-Col.) J. F. W. Sandison, M.C., R.A.M.C. (S.R.); Temp. Capt. (acting Maj.) T. V. Somerville, M.C., R.A.M.C.; Capt. T. A. Butcher, R.A.M.C. (S.R.); Maj. T. S. Dudding, R.A.M.C.; Maj. (acting Lt.-Col.) W. Lapsley, I.M.S.

To be Brevet Major.—Capt. H. C. Rook, R.A.M.C. (S.R.); Capt. C. S. P. Hamilton, D.S.O., R.A.M.C.; Capt. (acting Lt.-Col.) H. R. B. Gibson, I.M.S.

D.S.O.—Maj. A. Irvine-Fortescue, R.A.M.C.

M.C.—Capt. J. J. Magner, R.A.M.C.

BROUGHT TO NOTICE.

The names of the following medical officers are brought to notice for valuable and distinguished services rendered in connexion with operations in North or South Russia or in Persia. All are of the R.A.M.C. except where otherwise stated :—

Capt. F. B. Beatson, I.M.S.; Lt.-Col. (temp. Col.) C. H. Bowle-Evans, C.M.G., I.M.S.; Temp. Lt. F. C. S. Bradbury; Capt. T. A. Butcher; Maj. A. Cameron, I.M.S.; Temp. Capt. (acting Maj.) T. E. Coulson; Maj. T. S. Dudding; Capt. C. M. Finny; Capt. (acting Lt.-Col.) D. C. L. Fitzwilliams; Capt. (acting Maj.) H. R. Friedlander; Capt. (acting Lt.-Col.) H. R. B. Gibson, I.M.S.; Temp. Capt. (acting Maj.) R. T. Grant; Maj. (acting Lt.-Col.) H. Hallilay, I.M.S.; Capt. W. E. Hodgins; Capt. J. Hope; Capt. (acting Maj.) L. E. Hughes, M.C.; Temp. Capt. (acting Lt.-Col.) E. R. Hunt; Maj. A. Irvine-Fortescue; Maj. (acting Lt.-Col.) A. W. A. Irwin; Temp. Capt. (acting Lt.-Col.) R. Jamison; Maj. (acting Lt.-Col.) G. A. Jolly, I.M.S.; Temp. Capt. N. Joshi, I.M.S.; Capt. (acting Maj.) C. G. G. Keane; Capt. T. Kennedy; Temp. Capt. R. N. Khosla; Maj. (acting Lt.-Col.) W. Lapsley, I.M.S.; Temp. Capt. (acting Maj.) A. H. Macklin, M.C.; Temp. Capt. (acting Maj.) E. S. Marshall, M.C.; Temp. Capt. P. N. Mitra, I.M.S.; Maj. (acting Col.) E. L. Moss, C.M.G., M.C.; Temp. Capt. J. H. Oonawala, I.M.S.; Maj. (acting Lt.-Col.) J. M. B. Rahilly; Temp. Capt. B. S. Rao, I.M.S.; Capt. (acting Lt.-Col.) T. H. Richmond; Capt. (acting Lt.-Col.) J. J. D. Roche; Capt. (acting Lt.-Col.) J. F. W. Sandison, M.C.; Capt. J. L. Schwartz; Temp. Capt. R. L. Sinclair; Temp. Capt. M. A. Singh, I.M.S.; Temp. Capt. (acting Maj.) T. V. Somerville, M.C.; Lt. (Temp. Capt.) G. E. Spicer, M.C.; Col. G. St. C. Thom, C.B., C.M.G.; Capt. M. D. Vint; Temp. Capt. (acting Maj.) J. D. Watson, M.C.; Capt. (acting Lt.-Col.) J. B. A. Wigmore.

The following, also of the R.A.M.C. except where otherwise stated, have been brought to notice for valuable services rendered whilst prisoners of war or interned :—

Lt.-Col. E. F. E. Baines, I.M.S.; Capt. R. C. Clifford, D.S.O., M.C., I.M.S.; Lt.-Col. P. H. Collingwood; Temp. Capt. H. M. Gilbertson; Temp. Capt. A. J. Gilfillan; Temp. Capt. R. W. Hodgson-Jones; Temp. Capt. J. L. Jackson; Capt. W. H. R. McCarter; Temp. Capt. A. T. I. Macdonald; Capt. S. S. Meighan; Capt. L. Murphy, D.S.O.; Maj. W. R. O'Farrell; Capt. C. E. Redman; Maj. J. Startin; Capt. A. Sutcliffe; Maj. W. I. Thompson; Temp. Capt. E. A. Walker; Capt. W. Warburton.

A communiqué has been issued from the War Office, dated Feb. 9th, containing a list of names, which will not be gazetted, brought to the notice of the Secretary of State for War for valuable services rendered, mostly in the United Kingdom, in connexion with the war. The names of the following medical men appear in the list :—

Lt. E. J. Bader, S.Afr.M.C.; Dr. G. Badgerow; Temp. Capt. E. B. Barton, R.A.M.C.; Capt. A. S. Barnes, R.A.M.C. (T.F.); Mr. W. H. Beaumont; Capt. E. C. Bradford, R.A.M.C. (T.F.); Maj. W. Bruce, O.B.E., N.Z.M.C.; Temp. Maj. A. Cambell, R.A.M.C.; Dr. E. H. Colbeck, O.B.E.; Mr. W. H. Cooke; Mr. C. Curd; Dr. M. B. Ferguson; Capt. E. E. W. Fisk, S.Afr.M.C.; Mr. R. F. Flood; Capt. C. R. Girdlestone, R.A.M.C. (T.F.); Temp. Capt. J. Graham, R.A.M.C.; Dr. A. S. Griffith; Mr. J. M. Harper; Dr. H. Henderson; Dr. A. Hodgson; Dr. L. Kidd; Dr. P. King; Maj. (acting Lt.-Col.) W. Kirkpatrick, R.A.M.C. (T.F.); Mr. F. Lace; Temp. Capt. A. W. Macgregor, R.A.M.C.; Dr. G. J. K. Martyn, Dr. E. Montgomery; Mr. J. M. H. Munro; Maj. (acting Lt.-Col.) W. Murray, R.F.A. (temp. Maj., R.A.M.C.); Maj.-Gen. Sir W. W. Pike, K.C.M.G., D.S.O., A.M.S.; Temp. Capt. A. H. Priestley, R.A.M.C.; Maj. A. G. Reid, R.A.M.C.; Mr. C. W. C. Robinson; Mr. G. J. Scale; Capt. A. L. Singer, N.Z.M.C.; Dr. C. Sturm; Temp. Capt. J. H. K. Sykes; Dr. E. C. Thompson; Lt.-Col. and Bt. Col. S. J. Thomson, R.A.M.C.; Temp. Capt. A. H. Ward, R.A.M.C.; Dr. A. M. Watson; Capt. R. W. F. Wood, N.Z.M.C.; Temp. Capt. A. E. Wynne, R.A.M.C.

ROYAL NAVAL MEDICAL SERVICE.

Temporary Surgeon-Lieutenants transferred to the permanent list of Surgeon-Lieutenants: R. Buddle, H. L. Douglas, H. A. L. Guthrie, J. F. Ainley.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. G. S. Crawford and Major M. G. Dill retire on retired pay.

Major W. Byam to be temporary Lieutenant-Colonel whilst specially employed.

The undermentioned Majors relinquish the acting rank of Lieutenant-Colonel: G. R. Painton, (Brevet Lieut.-Col.) C. W. Holden.

Temp. Capt. P. J. Lane relinquishes the acting rank of Major.

Capt. J. E. Rusby resigns his commission.

Capt. P. C. Field is restored to the establishment.

Captains to be Majors: F. R. Coppinger, A. C. Hammond-Searle, J. E. Ellcome, G. J. Keane, (Bt. Major) H. H. Blake, R. M. Dickson, (Acting Major) F. Worthington, A. L. Stevenson, B. Varvill, (Acting Major) J. W. Houston, (Bt. Major) A. Shepherd, W. J. Dunn, F. B. Dalgliesh, (Acting Major) S. G. Walker, C. E. L. Harding, (Acting Major) A. L. Foster, C. M. Rigby, (Acting Major) A. G. Wells, (Bt. Major) A. E. G. Fraser, W. H. S. Burney, T. E. Eves, L. Murphy, A. H. T. Davis, J. S. McCombe, W. J. Tobin, (Acting Major) C. McQueen, R. O'Kelly.

Temp. Capt. J. E. Thompson to be acting Major.

Lieutenants (temporary Captains) to be Captains: C. O. J. Young, R. N. Phease, C. B. C. Anderson, P. E. D. Pank, G. Moulson, W. J. F. Craig.

Captains resigning their commissions: J. W. O'Brien, W. Moodie.

Captains seconded for service under the Colonial Office: C. D. M. Buckley, W. C. Hartgill, T. J. L. Thompson.

Temp. Lieut. H. Abernethy to be temporary Captain.

Officers relinquishing their commissions:—Temporary Majors retaining the rank of Major: A. T. Duka, E. Swainston, W. Pearson. Temp. Capts. M. Murphy (on transfer to the Indian Medical Service), A. Jones (granted the rank of Lieutenant-Colonel), (Acting Major) H. B. G. Russell (granted the rank of Major), (Bt. Major) R. Bruce-Low (retains the Brevet rank of Major). Temporary Captains retaining the rank of Captain: E. N. Glover, J. W. Robertson, M. J. Murray, J. D. Doherty, W. G. Macdonald, R. F. Lunn, A. S. Morley, C. R. Smith, S. W. Allworthy, A. H. D. Smith, H. W. Bennett, F. O'B. Ellison, J. R. O'Brien, W. J. Oliver, C. F. Constant, A. V. Dill, W. Murphy, A. E. Clarke, H. F. Penman, A. M. Malcolmson, A. Trower, H. W. Hay, H. Coppock, H. A. Richards, G. Millar, J. A. F. Hatch. Temporary Honorary Captains retaining honorary rank of Captain: V. Ricci, A. H. Good.

GENERAL RESERVE OF OFFICERS.

J. W. O'Brien, W. Moodie, and J. E. Rusby, late Captains, R.A.M.C., to be Captains.

SPECIAL RESERVE OF OFFICERS.

Officers relinquishing their commissions:—Capt. A. G. S. Wallace (granted the rank of Major). Captains retaining the rank of Captain: J. P. Broom, H. M. Wharry, E. D. Roberts, H. J. Rice, D. M. Jones, W. H. Duff, P. Charnock, A. A. Fyffe, J. J. Landers, P. V. Anderson. Lieut. C. L. Hewer (retains the rank of Lieutenant).

TERRITORIAL FORCE.

Capts. (acting Majors) L. J. E. McHugh, F. R. Humphreys, A. E. P. McConnell relinquish the acting rank of Major on ceasing to be specially employed.

Capt. C. P. C. Sargent is restored to the establishment.

Capt. H. B. Porteous is seconded for service with the R.A.F.

ROYAL AIR FORCE.

Medical Branch.—Capt. F. C. Kempson to be acting Major whilst employed [illegible] Major.

Flight Lieut. A. S. Glynn to be acting Squadron Leader whilst employed [illegible] Squadron Leader.

The undermentioned Captains are transferred to the unemployed list:—C. R. M. Pattison, J. Souter, S. R. E. Davies, T. C. Backhouse, W. Enraght, J. E. Lascelles, H. W. Pigeon.

Dental Branch.—Capt. W. J. Singleton and Lieut. (acting Capt.) G. W. Allen are transferred to the unemployed list.

SUSSEX THROAT AND EAR HOSPITAL.—The new buildings of the Sussex Throat and Ear Hospital in Church-street, Brighton, erected in 1898, have outgrown their requirements—at least, for out-patients, who now number over 400 [illegible] month. Last year the total was 4809, an ever increasing number. Needless to say, the resources are taxed to the utmost, and the Management Committee is appealing for increased annual assistance, and also for donations towards erecting an additional wing. It would seem also that the in-patient department must be severely taxed in that there were 469 cases during 1919, as against 403 in 1918, the beds numbering 22. No death has occurred in the institution for two years.

"Audi alteram partem."

IS THERE A PARA-SCARLET FEVER?

To the Editor of THE LANCET.

SIR,—Dr. C. R. Box, in his letter in your issue of Jan. 31st, asks for an expression of experience as to the character of the cases of scarlet fever during the present prevalence. In respect of the occurrence of relapses, real or apparent, my experience at this hospital has been that they have not been more frequent than usual. When rubella is epidemic certain cases are invariably passed through the receiving rooms of fever hospitals as mild scarlet fever; consequently rubella breaks out in the wards amongst the scarlet fever patients, and some of the rubella cases erroneously admitted catch scarlet fever. But rubella has not been prevalent in London lately, nor is it now, so that such untoward results are not happening. The cases, therefore, have presumably been cases of scarlet fever. Until recently the bulk of the cases have been of a mild character, as Dr. Box states. But since the end of December there has been an increase in the proportion of cases of a severe type.

Since Dr. C. Dukes drew attention to what he believed to be another infectious and epidemic disease, the "fourth disease," now close on 20 years ago, I have been on the look-out for it; but I have never been able to satisfy myself of its occurrence. Scarlet fever is clinically, and also epidemiologically, a very variable disease, with aberrant forms—namely, without pyrexia, without a rash, without peeling, with little or no sore-throat, &c.; and as has been pointed out by Dr. F. G. Crookshank in a very recent paper read before the Epidemiological Section of the Royal Society of Medicine, it is just in epidemic times that atypical cases of epidemic diseases are brought to light. Scarlet fever is so widely and continuously prevalent a disease, and its mode of dissemination is of such a kind, that it should be possible to prove the existence of a para form (if it exists more than sparsely), from clinical observation—that is, if it be the case that the ordinary and th paraform do not protect against one another.

By the way, is it asking too much to appeal to Dr Box and other writers to discard the term "Germa measles"? The disease is neither German nor measles as the latter word is now understood. The late Loca Government Board lost a splendid opportunity of gettin rid of this misnomer a few years ago, when it issue certain administrative orders relating to measles.

I am, Sir, yours faithfully,

E. W. GOODALL.

North-Western Hospital, Hampstead, N.W.,
Feb. 7th, 1920.

PHYSIOLOGICAL PRINCIPLES IN TREATMENT

To the Editor of THE LANCET.

SIR,—I much appreciate the kindly and sympatheti review of the fourth edition of my "Physiologica Principles in Treatment" which appeared in you columns on Jan. 21st. May I, however, reply to tw minor criticisms contained therein? The metaphor c "potassium iodide ferreting out the toxins which lur in lymph spaces"—which I quoted from Dr. Leonar Williams—may be more vivid than precise, and yet th meaning seems clear. The problem is to explain hov iodide lowers blood pressure in certain cases of hype piesis although it has no effect on normal bloc pressure. The suggestion is that it may help t eliminate pressor toxins as it does the syphilitic toxins The work of Barger and Dale has proved the existenc of such pressor toxins.

With regard to the remark that "it is not the author fault that acidosis has jumped off on another track (an perhaps run away altogether) since he wrote hi account of it" somewhat puzzles me; and so it do two well-known physiologists whom I have consulte The only generally accepted addition to our knowledg the subject is, I understand, Professor Haldane's proof of physiological acidosis occurring at high itudes. As I stated, my account of the newer develop- nts was based on Dr. E. P. Poulton's Goulstonian tures, which were published in your columns about ne, 1918, and Dr. Poulton is himself an original investi- or on the subject. It is true that hypotheses con- ning acidosis follow one another almost as swiftly as editions of an evening newspaper, but I think it is doubtful utility to burden the general practitioner h theories which are still in the controversial stage l which have not received general acceptance even ong laboratory workers on the subject.

I am, Sir, yours faithfully,
W. LANGDON BROWN.
avendish-square, W., Feb. 5th, 1920.

*** Dr. Langdon Brown's letter raises questions ich can only be satisfactorily settled by physician l physiologist in conference at the bedside. The dence that in hyperpiesis the lymph spaces contain ins seems to us to be at present very incomplete. e realisation that a diminished alkaline reserve in blood may mean either too much or too little d in the body, and that the condition of the od in this respect is no criterion of the con- ion of the body, further seems to us to alter whole conception of acidosis. But these plastic isiderations have hardly hardened sufficiently the written word. Physiological principles must ds change in advance of the therapeutic measures ed upon them, and it is Dr. Langdon Brown's cial merit that the latter do not lag unduly in his k.—ED. L.

THE SEX-INCIDENCE OF PERNICIOUS ANÆMIA.

To the Editor of THE LANCET.

IR,—In your report (THE LANCET, Jan. 31st) of the eting of the Edinburgh Medico-Chirurgical Society d on Jan. 21st, to which I communicated the ults of "An Inquiry Regarding the Age- and Sex- idence of Pernicious Anæmia," I am stated to have wn that the incidence of the disease "was distinctly re common in females than in males." My con- sions, eight in number, were read from the paper, l only one deals with this point. It is in the lowing terms: "Until the age of 50 the rate of idence inclines to be higher in the female than in the le. Thereafter the rate is definitely higher in males n in females."

made no statement regarding the mean rate for all iods of life in which a comparison was made between nale and male rates.

I am, Sir, yours faithfully,
eb. 7th, 1920. J. EASON, M.D.

THE INFECTIVITY OF TUBERCULOSIS.

To the Editor of THE LANCET.

IR,—Some points in Dr. H. Batty Shaw's address on erculosis (THE LANCET, Jan. 24th) have already n criticised in your last issue. Emphasis has been l on the infectivity of the disease, and as this is the x of the whole problem it seems clear that a ional scheme for prevention should now have our ious attention.

ll will agree that so long as our tuberculosis emes are based on the sanatorium they are bound fail in controlling the disease. One might go further l claim that any scheme for the treatment of erculosis of the lungs is foredoomed to failure ause death will be the inevitable result in the great jority of cases in which the disease has advanced so as to be evident on examination of the chest. In a ent report to the London Insurance Committee Dr. D. Bardswell shows that there is no appreciable longation of life in the majority of the applicants for atorium benefit in the London area, and our records Portsmouth show the same failure. Our present thods, then, are useless; when their cost is borne in mind they are worse than useless; and with a view to getting them altered tuberculosis officers everywhere ought to emphasise their poor results.

In the article referred to Dr. Shaw suggests that experimental work be done in the direction of (1) giving tuberculin to children before they are infected with tuberculosis; (2) vaccination against catarrhal infections in cases of tuberculosis. Is it his considered opinion that the adoption of these methods will be likely to lower the tuberculosis death-rate, especially when there is so little ground for the hope that tuberculin given to children before they have tuberculosis will substantially increase their resistance to the disease? In emphasising his theory that the immediate cause of the manifestations of tuberculosis in later life is auto-infection he seems to forget that infection originally is the cause of the disease, and if infection is stopped the subsequent auto-infection would be impossible. It is splitting hairs to draw fine distinctions as to when the infection may possibly take place. Let us emphasise rather that all tuberculosis is an infection, and that the logical means of controlling the disease is to try to prevent the further spread of this infection. In the present state of our knowledge prevention is the obvious line of advance, and not the elaboration of still further methods of treatment of doubtful value, methods which, after all, are based on his theory. Prevention is what the country is paying for, and it has never really been tried.

The tubercle bacillus gains access to man from two main sources: (1) through milk; and (2) from human infection.

(1) *Milk.*—It is generally accepted that the importance of milk in causing tuberculosis has been overrated, but it still remains a probable source in some cases. Ten per cent. of our milk contains the tubercle bacillus. The tuberculin test enables us to find the infected cows, and it should be an easy matter to clean up our herds, but we go on swallowing this infected milk and giving it to our children.

(2) *Human infection.*—Until segregation in large districts is adopted for all infective cases we are not attempting to deal with this source of the disease. Sooner or later this must be done, and if not done by us the next generation will do it. Dr. Shaw insists that there shall be no interference with the liberty of these infective cases unless generous treatment be provided. But if the community does all it can for them they ought to do something for the community; and if their presence in the community causes 140 deaths every day in England, in addition to an almost incalculable sickness-rate, the community can reasonably demand the removal of this danger, especially if it combines measures for its own protection with the best possible conditions for the prolongation of the lives of the victims. These conditions cannot be given in our midst where the struggle for existence is such that those with damaged lives cannot survive; they can be given only in districts specially set apart for the accommodation of tuberculous persons. The sanatoriums, hospitals, colonies, and other treatment centres could be collected together into, say, half a dozen large districts in the country, and encouragement given to all infective cases to settle in these districts. Free land, buildings, fuel, and a monetary grant per head could be given. Families could be admitted conditionally. The whole internal administration of the district should be managed by the patients themselves, including their marriage laws, manufactures, trade-unions, medical treatment, &c. Production would be carried on, though the district could not be entirely self-supporting. With such a scheme many difficulties would solve themselves, such as that of obtaining suitable employment after sanatorium treatment, and so heavily is the tuberculosis subject handicapped in getting suitable work that this reason alone would popularise such a scheme. There need be no fear that it would lead to concealment of disease provided reasonably generous conditions were given to these within the districts, as the outlook then for the patient would surely be preferable to being driven to the Poor-law infirmary in the last stages of his disease and his financial resources.

The cost of such a scheme when some production was carried on, and when the economy resulting from centralised administration is considered, could hardly be more than our present expenditure, directly and indirectly, on the tubercle bacillus. Compulsion would come later on when sufficient accommodation was available, when the inducements given in the district had popularised, and all infective cases would then be compelled to live in the district. The difficulties are great, but they are not insuperable; they must be overcome, and the Ministry of Health cannot better celebrate its birth than by tackling them. By all means let us eliminate as far as possible the predisposing causes of tuberculosis, and the greatest of these is bad housing; but until effective steps are taken to remove the massive doses of the exciting cause tuberculosis will continue to flourish.

I am, Sir, yours faithfully,
J. FAIRLEY,
Feb. 2nd, 1920. Tuberculosis Officer, Borough of Portsmouth.

AN OMISSION IN THE MEDICAL DIRECTORY.

To the Editor of THE LANCET.

SIR,—By a clerical error the name of Dr. E. Hyla Greves, of Rodney House, Bournemouth, was accidentally omitted from our current issue. Will your readers kindly note this?—Your obedient servants,

THE EDITORS OF THE MEDICAL DIRECTORY.
7, Great Marlborough-street, London, W.1, Feb. 10th, 1920.

Obituary.

LAURENCE HUMPHRY, M.D., F.R.C.P.,

PHYSICIAN, ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

BY the death of Dr. Laurence Humphry, which occurred on Feb. 5th, the Cambridge Medical School has suffered a great loss, one that for the present, at any rate, seems irreparable. Dr. Humphry was mobilised at the 1st Eastern Hospital at the beginning of the war, and gave himself to his exacting duties with unselfish devotion. By no means a strong man his periods of rest were brief and infrequent; thus, as the war wore on, especially in the last year or two, his friends noticed that the strain was telling upon him. He looked thin and worn, yet still loyally worked on. In this susceptible state Humphry became affected by some obscure septic virus which, beginning in the tonsils, gradually spread to other parts in a long and painful illness, during which the hope of recovery faded away. He died at the age of 63.

Dr. Humphry was a nephew of Sir George Humphry, and inherited much of the family ability. His father was a London barrister-at-law, Laurence being born at Richmond. His mother was a daughter of Dr. McNab, of Epping, a physician of some eminence in his day. In 1889 he married Isabel, daughter of the late Professor Sir George Stokes. They had no children.

Humphry graduated at Cambridge from Trinity College in 1876, taking his M.B. four years later. He did his clinical work at St. Bartholomew's Hospital, and by his uncle's advice returned to settle in Cambridge, and soon began to build up a consulting practice in medicine. In later years, as his senior colleagues died or withdrew from the harder work, Humphry became the leading consultant in the district. He was physician to the Addenbrooke's Hospital, and had filled the offices of assessor to the Regius Professor of Physic, examiner in medicine to Cambridge and other universities, and served on the Council of the Royal College of Physicians of London. As teacher of pathology and lecturer in medicine he took an active part in the medical school, in which he was keenly interested. For 15 years—years of much change and revision—he was secretary to the Special Board of Medicine, a post to which he was admirably adapted. He was orderly and accurate in business, thoroughly familiar with the somewhat complex affairs and procedures of the University, and thus, and by his personal qualities, carried not a few difficult and thorny measures through the Special Boar and the Senate.

Humphry, who had considerable talent for research at one time took charge of the Pathological Museum He was especially interested in malformations o the heart, on which subject he wrote the articl in Allbutt's "System of Medicine." He made som researches also on the functions of the pancreas on the parathyroid glands, and on embolic aneurysm of the pulmonary artery. He often regretted that h could not do more research work, but he was liable t frequent and intense attacks of migraine which mad sad inroads upon his time and energy. As a clinica physician he was excellent; sympathetic, gentl learned, and sagacious; moreover, he was well equippe on the scientific side of pathology.

Humphry was a man of rare charm of character modest almost to self-effacement, high-minded, gentl and with a keen sense of humour; but none the les decisive and wise in judgment. He was a chivalrou colleague and an affectionate friend. He had muc taste and skill in the fine arts, in which he and his wif also had no little accomplishment. He was skilful i modelling in wax, especially his medallion work in lo relief was very delicate and refined. During the earlie part of his illness he found in this work much relie from ailment and ennui. He was a skilful and almos an enthusiastic fisherman. He passes away deepl regretted.

CECIL R. CHAWORTH LYSTER, C.B.E., M.R.C.S.

MEDICAL OFFICER IN CHARGE OF ELECTRICAL DEPARTMENT, MIDDLESEX HOSPITAL.

WE briefly recorded a fortnight ago the death of M C. R. C. Lyster, which occurred on Jan. 26th, at the ag of 60. Mr. Lyster until within a few months of hi death was in charge of the X ray and electro-therapeuti department at the Middlesex Hospital, a post which h had held for the past 17 years. He received his medica education at Charing Cross Hospital, and subsequentl became the medical superintendent at Bolingbrok Hospital, an institution he did much to foster, an with which he continued to be intimately associate until the closing year of his life.

Mr. Lyster's services to medicine, and especially t medical radiology, were many. His publications wer few, and, indeed, form no guide to the many service he so freely rendered to the cause of humanity. It i essentially in the cause of humanity that his wor should be adjudged. At the time when he began t take an executive interest in the therapeutic and dia gnostic use of X rays little was known of thei potentiality and still less of the dangers attendin their use. It was during this period that he suffere from the first effects of continued exposure to fractiona doses of the rays he was using, especially in the trea ment of cancer. The damage that he suffered wa progressive in character and eventually developed int cancer, to which he succumbed. He knew some year ago that a continuation of his work would entail add tional risks to himself, but nothing could dissuade hi from continuing to devote his energies towards alleviat ing the sufferings of others, and the work of his lat years must be viewed in the light of a real sacrific The heavy demands of the war upon his services wer cheerfully met. He undertook the responsible positio of head of the X ray and electrical department at th Army Headquarters at Millbank, though the addition strain which this work involved was a very heavy on The honour of C.B.E., conferred on him in recognitio of his work, came too late.

Mr. Lyster did much to raise the status of medic radiology, and it was largely due to his efforts in th first place that a diploma of radiology and electrolog under the ægis of Cambridge University, became a accomplished fact. He was President of the Electr therapeutic Section of the Royal Society of Medicin during 1918–19, and served on its council for a numb of years. His breadth of outlook and unselfishne guaranteed a great respect among his colleagues for h views or proposals.

r. Lyster was a man who thoroughly understood his ow-man, and was a large-hearted man in every ect. His personal charm and lofty character were reciated by a wide circle, who will feel their loss very nly.

WIN LINDSAY DUNN, B.A., M.B., B.CH. DUB.,

LATE MEDICAL SUPERINTENDENT, BERKSHIRE ASYLUM,
WALLINGFORD.

dwin Lindsay Dunn was born in 1865, the son of the Mr. Robert Dunn, of Dunfield, Waterside, Ireland, received his early education at Foyle College, donderry, winning a scholarship in 1876. After uccessful schooling he entered Trinity College, lin, as first junior exhibitioner in 1882, taking his . degree with honours in classics and English rature. He then decided upon medicine as a pro- ion, and graduated M.B., B.Ch. in 1887 with ours in anatomy. He was appointed assistant se surgeon to the Children's Infirmary, Liver- l, assistant surgeon, Liverpool Dispensaries, and, n adopting lunacy practice as a career, assistant lical officer at the West Riding Asylum, Wake- l. At the Wakefield Asylum he made several tributions to medical literature, including "Cases of lepsy Treated by Amylene Hydrate," "Case of tening of Sensory Tract of Internal Capsule," and ase of Homonymous Hemianopsia." His paper on aranoia," read at the Psychology Section of the tish Medical Association at Nottingham in July, 2, was a noteworthy addition to our knowledge of t disease, although cases had been recognised in gland before then. In 1894 he was appointed senior istant medical officer and deputy medical super- ndent of the Berkshire Asylum, Wallingford, and the death of Dr. J. W. A. Murdoch succeeded him medical superintendent.

utside his professional work, literature, Free- sonry, and sport made their appeal to Dunn. At ool he was a member of the fifteen and a good ner; at Trinity College, Dublin, a prominent oarsman, ing for the University Boat Club and winning many es, and a member of the University fifteen. He also yed for the famous Wanderers Club, but although l in the running for the honour was not capped for land. He was fond of shooting and golf and a good erman, his proudest trophy being a fine Thames t, scaling 7½ lb., which he caught at Pangbourne. was well read, talking with knowledge and originality politics and religion—his knowledge of the Bible was found. He read Greek for pleasure and was fond of nch literature.

friend writes: "A true Irishman, genial, quick- pered, impulsive, generous to a fault, the soul of pitality, excellent at repartee. His laugh was in- tious; no one who heard it could forget it. He had a ius for making and keeping friends, and his jovial e, merry blue eye, and inimitable laugh will be sadly sed."

lis death occurred after several weeks of pain ne with fortitude. Dr. Dunn was unmarried. The iting committee of the asylum were his personal nds, and he was beloved by patients and staff, to om his sympathy and advice were always open.

R JAMES GRANT, M.D. MCGILL, M.R.C.P. LOND.

EW men can have lived a fuller or more varied life n James Alexander Grant, who was born at Inver- s in 1831 and died at Ottawa on Feb. 8th last. In the xties," after suffering himself from surgical blood- soning, he was led to test the effect of vaccine lymph various skin diseases, thus foreshadowing the later ults of serum therapy. A medical graduate of McGill, F.R.C.S. Edin., and M.R.C.P. Lond., he presided at time over the College of Physicians and Surgeons in tario, and at another over the Royal Society of nada. His political career included the introduction the Legislature of the Pacific Railway Bill. As a logist he held a position of some eminence. Knighted the height of his public reputation, he lived for years in well-deserved enjoyment of the honour.

Medical News.

A WORLD CONGRESS OF PHYSICIANS AND SURGEONS. —Dr. F. F. Simpson, with introductions from some of the chief representatives of medicine and surgery in the United States, is in London to consult with our leading men in the profession as to the coördinating and standardising of all branches of medicine so as to form a World Congress of Physicians and Surgeons, composed of the various international congresses and associations already established. The creation of international associations to deal with specialties which are not already thus provided is also to be considered. A meeting will be held to-day (Friday, Feb. 13th), at 5.30, at the House of the Royal Society of Medicine, and it is hoped also to arrange for conferences in Paris, Brussels, and Rome at early dates.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At recent examinations for the Diploma in Public Health the following candidates were recommended for the diploma:—

Geoffrey Andrew Bird, St. Thomas's and Middlesex; Kathleen Lydia Cass, Univ. Coll.; Frederick Adderley Howard Clarke, St. Bart.'s and R.A.M. College; Sheldon Francis Dudley, St. Thomas's; Walter Egbert Fox, Guy's; Henry Cecil Jennings, St. Thomas's; Ralph De Veil King, Univ. Coll. and St. Mary's; Alexander Frank Knott, Guy's; Bessie Russell MacKenzie, Edinburgh and King's Coll.; Rees Phillips, Middlesex and Univ. Coll.; Carrie Sims, Birmingham and Univ. Coll.; Hector Smith, Univ. Coll.; John Stewart, Glasgow; John Reginald Arthur Digby Todhunter, St. Thomas's and Univ. Coll.; and Frederick Norman White, St. Bart.'s and Univ. Coll.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH. —A quarterly meeting of the College was held on Feb. 3rd, Sir Robert Philip, the President, in the chair, when M. Eleutherios Venizelos, Prime Minister of Greece, was elected an Honorary Fellow, and Mr. Leo Ferdinando Bianchi and Dr. William Hughes were elected Fellows. The following were admitted to the Membership of the College: Dr. D. H. D. Cran, Dr. P. C. Davie, Dr. H. C. Elder, Dr. D. Cook, and Dr. E. W. Frecker. Licences to practise were granted (in conjunction with the associated bodies) to 11 candidates who had fulfilled the conditions and passed the Final examination.—The President announced that the Supplementary Royal Charter, dated Dec. 3rd, 1919, had now been delivered, and empowered the College to admit women to the Membership and Fellowship of the College on the same conditions and with the same privileges as men.—Sir Robert Philip was appointed a Trustee of the College.

COMPLIMENTARY DINNER TO SIR BERTRAND DAWSON.—Dr. Addison, the Minister of Health, and Sir Robert Morant will be present at the complimentary dinner offered to Sir Bertrand Dawson on his elevation to the peerage by the Federation of Medical and Allied Societies. All communications should be made to the secretary, Dr. Howard Mummery, at the offices of the Federation, 5, Vere-street, Cavendish-square, W. 1.

COMPLIMENTARY DINNER TO SIR GEORGE MAKINS. —A complimentary dinner will be given to Sir George Makins on a date in May which remains to be fixed. Sir Cuthbert Wallace will be in the chair, and St. Thomas's men, as well as medical officers who were associated with Sir George Makins in the B.E.F., are asked to communicate with Mr. C. Max Page, 134, Harley-street, W. 1, if they desire to be present. Final arrangements can then be made, of which due notice will be given.

THE TUBERCULOSIS SOCIETY.—At a general meeting of the members of the Tuberculosis Society it was decided that the society should not affiliate with the Federation of Medical and Allied Societies. As far as medical societies are concerned, the Tuberculosis Society considers that a subcommittee of the British Medical Association could ascertain their views. On the ascertainment of the views of the public the Tuberculosis Society is silent.

H.R.H. Princess Mary will lay the foundation-stone of a nurses' home in the grounds of the Royal Hospital and Home for Incurables, Putney, on Wednesday, May 12th. The Princess has consented to receive purses, containing 5 guineas or upwards, towards the cost of the new building from ladies and young people who will have the honour of presenting their gifts at the foundation-stone laying ceremony. An album in which will be given the names and postal addresses of those presenting the purses will be prepared for Her Royal Highness. All wishing to give purses should write at once to the secretary of the Royal Hospital and Home for Incurables, Putney, at the City offices, Bond Court House, Walbrook, E.C. 4.

THE Preston and County of Lancaster Queen Victoria Royal Infirmary have received from Lord Ashton [illegible] gift of £5000.

AN Order has been issued under the Anthrax Prevention Act, 1919, prohibiting, on and after Feb. 9th, the importation into the United Kingdom of shaving brushes manufactured in or exported from the Empire of Japan.

THE President of the French Republic, M. Poincaré, late Rector of the University of Glasgow, has conferred the Cross of Officer of the Legion of Honour upon Dr. James H. Nicoll, consulting surgeon to the Western Infirmary and Rector's Assessor in the Glasgow University Court from 1914 to 1919. Dr. Nicoll has been granted the Royal permission to accept and wear the decoration.

THE Ministry of Health is now making grants in aid of the blind, and with a view to coördination of effort has secured the close coöperation of the National Institute for the Blind, of which Sir Arthur Pearson is President. A Joint Committee representing the Advisory Committee on the Welfare of the Blind which sits at the Ministry and the National Institute for the Blind has accordingly been set up, and a desire is expressed that ways of diminishing overlapping and of preventing waste of effort in the collection of voluntary contributions shall, among other things, be considered.

ROYAL INSTITUTION.—On Tuesday next, Feb. 17th, at 3 o'clock, Professor Ernest Wilson begins a course of two lectures at the Royal Institution on Magnetic Susceptibility. On Saturday, Feb. 21st, Professor Sir J. J. Thomson begins [illegible] course of six lectures on Positive Rays. The Friday evening discourse on Feb. 20th will be delivered by Dr. E. J. Russell on British Crop Production, and on Feb. 27th by Mr. W. B. Hardy on Problems of Lubrication.

MANCHESTER MEDICAL SOCIETY.—The Presidential address of Professor R. B. Wild, which was delivered on Feb. 4th, had the comprehensive title "Some Racial Problems, Social Evils, and Modern Crusades." The racial problems concerned the falling birth-rate and its accentuation by the war, and general eugenics, as well as the care of the feeble-minded, were briefly discussed under this heading. The effects of tuberculosis, cancer, gout, and venereal diseases upon the race, [illegible] opposed to their effects upon the individual, were considered, [illegible] well as the prevalence of certain drug addictions—alcohol, caffeine, and nicotine—whose causes and results were compared and reviewed in an interesting dissertation.

CENTRAL COUNCIL OF INFANT AND CHILD WELFARE WORK.—At a meeting held at the Mansion House, London, on Feb. 4th Sir Arthur Stanley announced that the sum of £10,000 had been received by the Central Council as the result of the Victory Ball. This sum, though a happy and auspicious beginning, was [illegible] mere drop in the ocean compared with what was needed. Twelve existing societies connected with the furtherance of infant welfare had agreed to combine, and the aim of the Central Council was to do nothing that would diminish the strength and individuality of its component societies, but to get the money necessary for their work, and intervene only to prevent waste and overlapping.

GRANT TO THE VILLAGE CENTRES COUNCIL.—Queen Alexandra has decided to bestow with certain limitations the interest which will accrue annually from the surplus of £3000 from the Queen Alexandra's Field Force Fund to the Village Centres Council for the benefit of the disabled ex-Service men at their first village centre at Enham, in Hampshire. This will enable the relief which her fund sent abroad during the war years to continue and to benefit the victims of that war and fit them for usefulness in days to come. The Council is at present giving 150 ex-Service men medical treatment combined with curative and vocational training. The Committee hope to accommodate eventually 500 men. The present centre owes its inception to voluntary generosity, which is now supplemented by a capitation grant received from the Ministry of Pensions for each patient, and it is hoped that when the numbers reach 225 these fees, together with the produce sold from gardens, farms, and workshops, will place Enham on a self-supporting basis, though capital will still have to be found for further extension and a cottage scheme. The Executive Committee is at present considering the best way of laying out the annual amount which they will receive from Queen Alexandra's Field Force Fund.—The town of Southampton is increasing its donation of £500 for the Southampton Hut at the Enham Village Centre to £1000, and the city of Winchester has also contributed the sum of £500 for a Winchester Hut. It is hoped that many other cities in the United Kingdom will follow the lead given by Southampton and Winchester. Full particulars regarding the work of the Village Centres Council can be obtained from the secretary at 51, Lincoln's Inn Fields, London, W.C. 2.

Births, Marriages, and Deaths.

BIRTHS.

ELLIOTT.—On Feb. 6th, at the Richmond Hill Nursing Home, Aberdeen, the wife of Walter Armstrong Elliott, M.B., B.S., of a daughter.

GILLIATT.—On Feb. 5th, 1920, at 58A, Wimpole-street, London, W., the wife of W. Gilliatt, F.R.C.S., of a daughter.

KENNEDY.—On Feb. 4th, at Boughton, near Faversham, Kent, the wife of Arthur Kennedy, M.A., M.B., Ch.B., of a daughter.

O'NEILL.—On Jan. 8th, at Meerut, the wife of Major J. S. O'Neill, M.C., I.M.S., of a daughter.

MARRIAGES.

HUMPHREYS—HUDSON.—On Feb. 5th, at Knowle Parish Church, Humphrey Humphreys, M.C., M.B., to Constance Hudson, eldest daughter of Mrs. R. B. Cooper, of Knowle.

MACINNES—WOOD.—On Feb. 6th, at St. John's Wood Presbyterian Church, London, John MacInnes, M.B., to Mabel Maude, daughter of Richard Wood, Esq., New South Wales.

ROBINSON—MACDONALD.—On Feb. 3rd, at the Congregational Church, Barnsley, Captain Christian Cathcart Robinson, R.A.M.C. (T.F.), to Jessie Leonora, second daughter of Mr. Allan Macdonald, Oaklands, Huddersfield-road, Barnsley.

DEATHS.

CLERY.—On Feb. 10th, at St. John's Park, Blackheath, S.E., Surgeon-General J. A. Clery, C.B. (retired), late A.M.S.

HUMPHRY.—On Feb. 5th, at Lersfield, Cambridge, from illness contracted while on service at the 1st Eastern Hospital as Lieutenant-Colonel, R.A.M.C. T., Laurence Humphry, M.D., F.R.C.P., Senior Physician to Addenbrooke's Hospital, aged 63.

LAKE.—On Feb. 8th, at Benton, Teignmouth, William Charles Lake, M.D., aged 94.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

tes, Short Comments, and Answers to Correspondents.

MAN'S ORIGIN.

IE last of a series of lectures[1] on the origin and distribu- of man upon the earth was given by Professor G. ot Smith at the Royal Institution on Feb. 10th. The ortance of gold has loomed large to the public attention ecent years, yet its place in primitive society, thousands ears before it became the basis of currency, was certainly less influential.

The Search for Gold : the First Explorers.

ie story of an ethnological discovery of revolutionary ort, connecting the spread of the earliest civilisation with 's search after gold, was told with graphic interest—an rest which was heightened by the fact that the urer himself had played so large a part in unveiling records of the distant past. It was in 1908 that fessor Smith, researching amongst the mummified ains of early civilisations in Egypt, discovered traces of lien population who had lived in that country shortly re the building of the Pyramids. A year later, when vas pursuing the investigation of this race, he found these people had also inhabited parts of France and at Britain, and that their residence was associated with erection of rough stone monuments (megaliths), of which nehenge is a type. A series of slides showed examples of e dolmens from Europe and also from India. It was in , when he was examining for the Natural Science Tripos Cambridge, that Professor Smith made a further nishing discovery. A skull had been put out for poses of examination, and he was interested to find this was [illegible] perfect example of the race into whose toms and travel he had been inquiring. To his amaze- it this skull proved to have come from the Chatham nds in the Antipodes, and to be only one of a collection skulls all bearing the same characteristics. This ouraged him to look still further afield for signs of this ple. In 1914 he was in Australia, and there found a mmy brought from the Torres Strait which was balmed in a peculiar way. The method was so charac- stic of that employed by this special race in Egypt that it ght be taken as conclusive evidence of the spread of their ticular culture. Moreover, it is found in all parts the world associated with the megalithic monuments. ny other customs and beliefs were found to be character- of these peoples, and assisted in locating with certainty se parts of the earth which they had inhabited. Amongst customs cited were those of piercing the ears for the port of special ornaments, tatooing, and the use of the stika, and the fairly prevalent custom amongst certain es of "couvade."

The Coincident Distribution of Gold.

n 1915 Mr. W. J. Perry, having received from Professor ith an account of his researches, drew the latter's atten- to the remarkable fact that wherever this early race of lorers had left the traces of their culture, there might be found evidences of a natural deposit of gold. Certainly re were some corners of the map where gold deposits had n marked, but no megalithic monuments reported. In ne of these an investigation revealed unmistakable lence, of the residence of this people—monuments and the characteristic terraced cultivation of the river banks. other places, [illegible] in the goldfields of the Transvaal and in stralia where gold was abundant, the marks of the lorers were wanting. Numerous maps were shown ving the remarkable close coincidence between the gold osits and the megalithic remains. Some of these maps e constructed from observations made by independent ervers before Mr. Perry had advanced his theory relating two sets of observations. Some idea of how the explorers velled was obtained from drawings of boats found on nze relics in Sweden and in the sculpture of the Egyptian galithic days. This type of ship was also found by nley on Lake Victoria Nyanza.

'he earliest historical records (the Vedas) refer to man as ng in territories which have also been located as the sites goldfields. Mithras worship is also found to follow the ne geographical plan. A modern map shows in its outlines same relation of occupation to mineral deposit. Thus Russian boundary is drawn to include the valuable nes to the north of Persia, while the Franco-Prussian r and the war just concluded illustrate further the dency of the dominant race to include minerals within limits of their territory.

The Paths of Discovery.

The connexion between gold and early civilisation, as already shown in Europe, Asia, and Australasia, was also demonstrated in the American continent. An outline was given of the direction in which these explorations after gold had spread. About 2500 B.C. the valleys between Turkestan and Persia had been exploited. Jade was found in the river-beds, [illegible] well [illegible] gold and pearls. Though the explorers attached no particular value to jade, the local inhabitants endowed it with the same magical properties as the gold and pearls. Influences of Babylonian culture were again evidenced in the banks of these streams. The early discoverers would have pressed on to N. China and there separated into two parties, one passing on to the valley of the Yenisei in Siberia to found there [illegible] colony of marauders that had proved a storm centre of the civilised world for 20 centuries. It was the pearl-beds that had lured the adventurers to the American side of the Pacific. Pearls were found on the islands in their track and the site of Copan, in Honduras, mentioned by Professor Smith on account of its precise evidence of old-world culture, was the one spot in that part of America where gold, silver, and copper were all to be found. The pioneers who went in search of gold had sometimes suffered from the reputation their wealth gave to them. They were attached by the ancient military aristocracies and enslaved, and so the evidences of their existence might sometimes be obscured.

How Gold Acquired its Charm.

An important and absorbing part of the story related how gold came to acquire so great an influence in the world. The earliest evidence of its use comes from Egypt and dates from about 4000 B.C. The ancient Egyptian symbol for gold is a conventional girdle of cowries. These shells still form part of the dress of certain tribes, and in the more recent Egyptian history were worn by princesses with gold and felspar to complete the girdle. The cowry shell was buried with the Egyptian dead. It was endowed in their belief with the virtue of vitality. It increased fertility, preserved youth, and was given to those who died in the belief that death was [illegible] sign of diminished rather than absent vitality, and that with this additional source of vigour the dead might carry on some sort of life beyond the grave. After a time the demand for cowries must have exceeded the supply for models were made in imitation of the real shells from the clay of the river bed. Then gold, also found in the river-beds, was used to make model cowries. The beauty and lustre must have confirmed their beliefs, till presently the substance rather than the form acquired a magical significance.

MEDICAL AFFAIRS IN JAIPUR STATE, 1918.

JAIPUR is an independent Rajput State, the capital of which, having the same name, is an important commercial centre; the population of the State in 1911 was 2,636,647, and of the capital, 137,098; the city lies about 150 miles to the south-west of Delhi. The climate is hot, but not unhealthy. The birth-rate in 1918 in Jaipur city was 20·2 per 1000, and the death-rate 72·97 per 1000; about one-third of this mortality occurred among children under 5 years of age.

The chief causes of death were fevers (5898), plague (1191), and respiratory diseases (820). The plague epidemic had completely subsided in the early part of June, but was severe while it lasted; there were 1199 attacks and 1196 deaths in Jaipur city and the plague camp hospital; and 18,150 attacks and 17,479 deaths in 331 infected towns and villages throughout the State. Influenza was also epidemic in a very severe form in October, and caused 4393 deaths; on Oct. 24th there were 265 deaths from this cause alone in Jaipur city. At the Mayo Hospital a total number of 29,240 patients were treated, of whom 2320 were in-patients. As many as 1032 major operations were performed, 963 of these being undertaken by Rai Bahadur Dr. Daljang Singh Khanka, including 471 for cataract. The number of prisoners in the central and district jails averaged 772, with an admission-rate to hospital of 182·6 and a death-rate of 49·21 per 1000; the admission-ratio is considerably lower than that for jails throughout India as a whole (706 per 1000, average 1906–15), but the death ratio is much higher (20·46 for India, 1906–15).

An interesting and valuable series of tables in the appendix give details of meteorological observations taken at the Jaipur Observatory. The mean temperature in 1918 was 77·4° F. (the same as the average for 50 years); in May the mean was 94·4° and in June 91·4°; the solar radiation thermometer registered 178° on May 15th, 174° on June 23rd, and 175° on July 5th; the highest shade temperature registered was 114° on May 15th. The total rainfall throughout the year was only 8·82 inches, compared with 51·86 inches in 1917, and a 50 years' average of 23·69 inches.

Jaipur is a flourishing and healthy State, hot in the summer and cold in the winter, but not nearly so extreme in either direction [illegible] Western Rajputana or the Punjab. The city is well built and its sanitation well cared for. The report under consideration, which is submitted by Dr. D. S. Khanka, assistant surgeon, is comprehensive and well arranged, and bears testimony to the enlightened administration of this independent Rajput State.

[1] A report of Lectures I. and II. appeared in THE LANCET of ɔ. 7th, p. 357.

THE POSITION OF POTASH SUPPLIES.

THE future of potash supplies is of the utmost importance to the agricultural interests of this country and therefore to the community at large, and it is disturbing to find that our own resources, so far as they have been exploited, prove to be short of requirements. Perhaps a useful and valuable lesson might be learned from what Germany has done in this matter. That country found long ago in the famous district of Stassfurth that there were great deposits of common salt left probably by the evaporation over an infinite period of time of [illegible] great sea incursion. The same thing, likely enough, happened in these islands, for we possess huge deposits of salt in Cheshire (Droitwich and Nantwich in particular) and in Stafford. In Germany it was argued that as potash was also a constituent of sea-water its salts probably would be found beneath the common salt layer. Continued boring proved that to be the case, and [illegible] centre of the world's supply was established. What this supply means may be judged from the following paragraph taken from the *Economic Review* (Jan. 21st) :—

Prospects of the German Potash Industry.

A report on the conditions of the potash industry during the war and its prospects, issued by Gebr. Dammann in Hanover, states that in 1913 2,483,000 d.ctr. of pure potash, to the value of over Mk. 100 mill., was exported to the United States out of a total sale of 11,100,000 d.ctr. This outlet was completely closed, but Germany's economic life was so strangled by the war that any danger of over-production disappeared. No new shafts were sunk during the war.

The geographical position of the Alsace deposit lays down definite limits for their future working. Germany's needs for agriculture and industry are undiminished, and she must also supply the enormous areas in the East; Northern Europe will scarcely enter into competition; the sales overseas, especially to the United States, will also fall principally to the German potash industry. Leading manufacturers are of opinion that under normal labour conditions the production can without difficulty be increased from the 11 mill. d.ctr. in 1913 to 20 mill. d.ctr., and the exploitation of the almost unlimited opportunities of sales abroad can contribute to the raising of the German exchange and the restoration of her economic life to a sound basis.

The average selling value of 1 d.ctr. of pure potash has increased from Mk.17.50 in 1913 to nearly Mk.29 in 1918—i.e., by about 70 per cent. The figures for 1919 are not yet to hand, but since the average home prices have increased during 1919 by a further 175 per cent., there will be a considerable increase in turnover to record in spite of the reduction in quantity, the sales probably reaching about Mk.500 mill.

During the autumn of 1919 the work of concentration has been going on. Out of 198 potash works more than 150 are now united into syndicates, and out of 40 new mines being opened 30 belong to similar concerns.

The fall of the exchange and the appearance of foreign buyers in the German share market has made itself increasingly felt in the potash industry.

As regards the future, the potash industry is especially adapted to aid in the reconstruction of Germany's economic life. It has no need to import raw material. The German deposits are so rich that without stinting home agriculture and industry they can supply all the civilised countries in the world. (*Hamb. Corr.*, Jan.6.e.)

Potash is clearly a magnificent asset to Germany, and the circumstances of the birth of the industry may well be worth enquiring into in regard to the great salt deposits in this country. Have our engineers, geologists, and chemists gone into this matter? The German view seems to have been that where there was sodium there must be potassium. It proved right. It seems to us we should start a similar quest in the depths of our great saline deposits. With any success both medicine and agriculture would profit.

A GLOUCESTERSHIRE CENTENARIAN.

Mr. Joseph Read, an inmate of the Thornbury Workhouse Infirmary, celebrated the 100th anniversary of his birthday on Jan. 28th. He was born at Winford, Somerset.

THE SOCIAL SERVICE LIBRARY.

Messrs. Bell will inaugurate next week the new "Social Service Library," which they are publishing in conjunction with the "Ratan Tata Foundation," under the editorship of of Mr. C. R. Attlee. The first volume deals with "The Social Worker," and is designed to some extent to serve as a general introduction to the series. Succeeding volumes will deal with "The Boy," "The Mother and the Infant," "The Girl," and "The Worker and the State." All of these are in active preparation and will, it is hoped, be published at short intervals.

CHILDREN AND CINEMAS.

THE question of injury said to be caused to children sitting too near the screen at picture theatres has been engaging the attention of the Eastbourne corporation, which invoked the assistance of Mr. N. Bishop Harman. In a report presented in conjunction with the medical officer of health of the borough, Dr. W. G. Willoughby, Mr. Harman says the optimum position is [illegible] nearly [illegible] possible in a line with the centre of the screen, and as far away from the screen as thrice its full height. In this position, and at such a distance, the picture appe more natural than in any other. But in nea all the cinemas in Eastbourne Mr. Harman discove the front seats were much too near the screen, the dista being equal to about once the height of the screen; as children were often relegated to the front rows pictures had an injurious effect on their eyesight. corporation have decided to include [illegible] clause on the li suggested by Mr. Harman on the issue of any new licenc

MEDICAL PENSIONS BOARDS.

To the Editor of THE LANCET.

SIR,—"Ex-R.A.M.C." in your issue of Feb. 7th pertine inquires how practitioners with large panels can find t to officiate on so many medical pensions boards. inquiry might with advantage be extended as to the met of appointment and qualifications of the hordes of med officials who are engaged in the Pensions Ministry f Whitehall downwards and the necessity for their existe Many of the pensioners have been out of the army for tw three years, or even more, and it is high time that perman pensions should be awarded them instead of re-board them over and over again. Further, the assessment sho be made in doubtful cases by those who have actually trea these men for weeks, or perhaps months, and who theref can best estimate their disability. The waste of pu money involved in maintaining the medical personnel in various regional areas (many doing clerical work t could be carried out [illegible] efficiently and more economic by clerks), with the accompanying galaxy of clerks typists, is appalling, and it would be interesting to know proportion of administrative charges to the amount actu reaching the pensioners' pockets or expended on t treatment.

I venture to think that such [illegible] return would effectu check the efforts now being made to saddle the coun with an enormous State Medical Service.

I am, Sir, yours faithfully,
Feb. 8th, 1920. PENSIONE

To the Editor of THE LANCET.

SIR,—I quite agree with "Ex-R.A.M.C.," who writes your issue of Feb. 7th that it is unfair that those of us have lost our practices through joining up should hav compete with men who have not served in the war in capacity. Some of us are on short time and employed f very few sessions weekly to make room for these men. T is contrary to the many definite promises made by Ministry of Pensions that preference would always be gi to those who had served at home or abroad.

I am, Sir, yours faithfully,
Feb. 8th, 1920. ANOTHER EX-R.A.M.

LIQUID PARAFFIN AS AN INTESTINAL LUBRICA

To the Editor of THE LANCET.

SIR,—It would be of interest to know whether any results have been observed in relation to the regular us paraffin as an intestinal lubricant. If paraffin oil be ta at or near [illegible] meal-time one would expect that, the food be thus intimately mixed with an inert mineral oil, there mi thus be interposed an obstacle to efficient digestion, u mately leading to varying degrees of malnutrition intestinal putrefaction, comparable with that which res from pancreatic insufficiency. As a corollary it would b the first importance that liquid paraffin should only taken late at night.—I am, Sir, yours faithfully,

Linden-gardens, W., Jan. 24th, 1920. PAUL C. GIBSO

⁂ The admixture cf a non-saponifiable oil with foo calculated to act [illegible] a barrier against the action of diges (hydrolysing) fluids. Even saponifiable fats do this, as i greasy meal. While petroleum lubricates the bowel it gi indigestion in some subjects.—ED. L.

METRIC DISPENSING.

To the Editor of THE LANCET.

SIR,—In reply to "W.," since the war many of us have into the habit of excluding Germany from our considerat in most matters. German regulations do not commit ot decimal-using countries to the same. The comma forms part of the decimal system proper, be it money, weights measures, and its use in connexion with such only tend complicate matters. The proper point is a full-stop rever —i.e., upside down, so as to appear at the upper part of figures. There is no necessity to denominate the fractio any amount which is already denominated by its relation the integer, thus 7 g 50 can mean nothing more nor l than 7 g 50 cg. The mode of expressing metric measure advocate renders mistakes practically impossible.

I am, Sir, yours faithfully,
Coulson-street, S.W., Feb. 4th, 1920. W. W. HARDWICK

Lettsomian Lectures

ON

TUMOURS COMPLICATING PREGNANCY, LABOUR, AND THE PUERPERIUM.

Delivered before the Medical Society of London on Feb. 2nd and 16th, and March 1st, 1920,

BY **HERBERT R. SPENCER**, M.D., B.S. LOND., F.R.C.P. LOND.,
OBSTETRIC PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL.

LECTURE I.—(*Abridged*).

FIBROID TUMOUR COMPLICATING PREGNANCY, LABOUR, AND THE PUERPERIUM.

GENTLEMEN,—A record of my experience, extending over 32 years, of tumours complicating pregnancy, labour, and the puerperium may not be without interest. I have limited the subject to fibroid tumour of the uterus, ovarian tumour, and cancer of the uterus; of the last two I have given the whole of my cases; of fibroid tumour, all the fatal cases and all the abdominal sections.

CASE 1.—A primipara, aged 35, seen in February, 1888. Married eight months and six months pregnant. Had a contracted pelvis, conjugata vera $3\frac{1}{16}$ in. Several uterine fibroids present: one on the left side of the body as big as a large watch, and another as big as a hen's egg on the left side of the lower segment, movable on a thick pedicle, and coming down as low as the vaginal fornix. I advised induction of labour at the seventh month. This was attempted by means of bougies, laminaria and sponge tents, and Barnes's bags; but, owing to the rigidity and small size of the cervix, without any effect. Finally, the cervix was dilated under chloroform with Barnes's bags and the child turned; craniotomy had to be performed on the after-coming head. The labour was a very difficult one, the patient being under chloroform for three hours. After delivery the uterus was found to have a large irregular mass of fibroids on the right side running nearly the whole length of the organ and causing it to reach, when involution was complete, within ½ in. of the umbilicus. The puerperium was perfectly normal.

I advised her if she became pregnant again to have a Cæsarean section. She did not return, but I was informed that she had several abortions procured in subsequent pregnancies.

SMALL TUMOURS GIVE RISE TO LITTLE TROUBLE.

Every obstetric physician in his private practice meets with many cases of small sessile subperitoneal fibroids of the size of a walnut to a lemon, as he attends an unusual number of elderly primiparæ in whom they are very common. In primiparæ of 35 and upwards I usually find one or more fibroids. These small tumours ordinarily cause no trouble of any kind. I append brief notes of the last case attended, which is typical of many.

CASE 2.—H., aged 38, married five years (children 0, abortion 0), 6 ft. 1 in. in height, in perfect health. A fibroid as big as a thick watch was found on the left side of the lower segment, and several small fibroids of the size of marbles and walnuts at the top of the fundus on each side. Labour at term, Oct. 11th, 1919, lasted 8½ hours; pains normal; delivery natural; no post-partum hæmorrhage. Child strong, 9¼ lb. Puerperium afebrile. The patient has not been informed of the existence of the tumours.

INNOCUOUS LARGE TUMOURS.

Even when large tumours are present it is remarkable how often patients pass through pregnancy and labour without serious trouble, as the following examples, selected from eight similar cases, show.

CASE 6.—T., aged 42, married eight years, never previously pregnant. Seen on April 26th, 1905. Pain in the right side of the abdomen of two months' duration. Nearly five months pregnant. Menstruation had always been regular, lasting three days, and usually preceded by pain.

The uterus was much larger than it should be, owing to a fibroid about as big as a fœtal head and a larger one as big as a coconut in the right cornu. (See Fig. 1.)

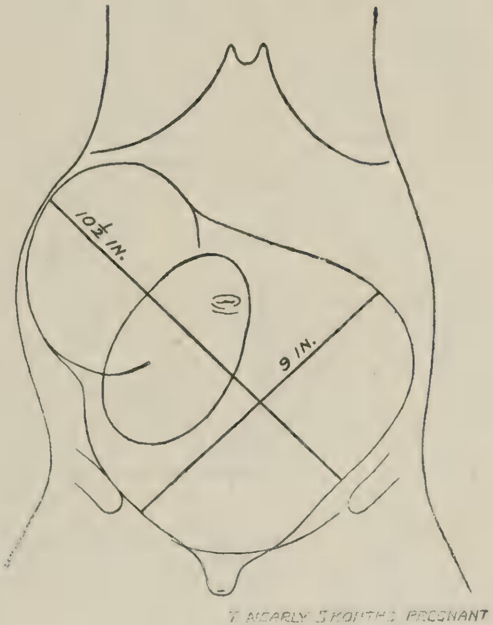

FIG. 1.—Case 6, showing two large fibroids.

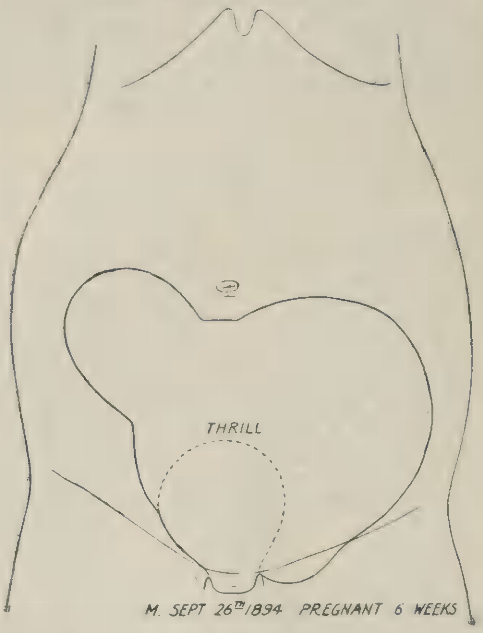
A girl was delivered alive (a breech presentation) by Dr. Pearce, of Ripley, on Oct. 2nd, 1905. The mother made an excellent recovery. The uterus contained such a large mass of fibroids that on the fourteenth day of the puerperium it measured 10½ in. transversely, and reached up for 1½ in. above the umbilicus. Fourteen years later, on Nov. 18th, 1919, mother and child were both very well. No pregnancy since. Menstruation regular till 1911, when she was 50 years of age. The uterus was then small and atrophied, freely movable, and, except a slight irregularity of its surface, no sign of the fibroids could be found.

CASE 7.—On Sept. 26th, 1894, M., a nullipara, aged 37, was sent to me by Dr. Lennox Wainwright, of Folkestone. Married twice, the first time at the age of 20; but although married many years to her first husband, no coitus had occurred. Her second marriage took place July 1st, 1894. A few days afterwards she had a period, but none since. In the last three days she had been sick, and for three weeks she had had frequency of micturition. At the age of 14 she had an attack of peritonitis, which was repeated in 1886 and 1892, and since then had had several threatenings, and a well-marked attack three weeks ago. Menstruation began at the age of 11, and was regular except at the age of 19, when it stopped for 13 months; it was always very painful.

On examination the abdomen was tender and distended by a tumour, which reached up to the umbilicus on the left side and rather higher on the right, where there was a marked movable projection as big as a fist. The tumour felt like a myoma and near the middle of it there was a marked thrill. The uterus was retroverted, apparently enlarged, and seemed to pass into a hard mass above and around the cervix. To the left of the cervix projected a solid mass connected with the uterus, which came down to the level of the edge of the cervix. The diagnosis was made of pregnancy of 2 to 2½ months complicated with multiple fibroids. With rest the patient progressed fairly well, but on Oct. 28th, 1894, I was called to Folkestone and found her extremely ill, vomiting frequently, and obstinately constipated. A large enema of soap and water was successfully administered and the patient recovered completely. At this time the fundus had then risen out of the pelvis, but the fibroid on the left side still occupied the brim. At the beginning of April, 1895, the patient came to London with a view to a Cæsarean section. The head was above the brim and the lower end of the large fibroid just entered the pelvic brim on the left side, otherwise the pelvis was free and of full dimensions. The urine contained much albumin, and on consultation with Sir John Williams it was decided to induce labour on this account. This was done with bougies. During the labour the fibroid on the left side retracted above the brim and a well-developed girl of about 8½ months' development was born alive, after a normal labour, on April 7th, 1895.



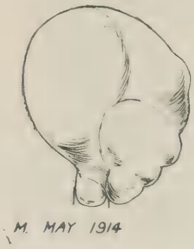


FIG. 2.—Case 7. The larger figure shows the size of the tumours at the sixth week of pregnancy; the smaller figure shows the size of the uterus 20 years later.

On May 7th, 1914, I saw the mother, aged 57, in good health. Menstruation stopped at the age of 47. The uterus was of the size of a fist, hard, and of the shape shown in the diagram. (See Fig. 2.)

CASE 8.—T., aged 26, consulted me in 1893 for dysmenorrhœa of three years' duration. The pain occurred a week before and during the whole of the period, which used to last eight days and lately six days. The uterus was small, the body a little irregular on the right side owing to the presence of a small fibroid. There was a body twice the size of an ovary on the left side; this was evidently the large fibroid found later. The right side of the lower segment also felt hard, as if from the presence of a small fibroid.

After she had been married 3½ years she was sent to me by Dr. F. W. Lyle, of Ealing, on June 12th, 1899. Although only three months pregnant (for the first time), the uterus reached up to a height of 6½ in. above the pubes, owing to the presence of three fibroid tumours the largest of which was nearly as big as a child's head the smallest encroaching upon the brim on the righ side. She was delivered by Dr. Lyle of a living chil on Jan. 12th, 1900, 297 days after the last day of the las period, and recovered well. She was again delivered with low forceps, of a living child, which weighe 9 lb. 7 oz., on Dec. 28th, 1903, 287 days after the las period. The labour lasted 5¾ hours. Mother and childre alive and well on Nov. 5th, 1919. No further pregnancies She had begun to menstruate at the age of 14, and stil menstruated (at the age of 52).

CASE 12.—S. H., a nullipara, aged 36, had a larg tumour in the upper right wall of the uterus (se photograph, Fig. 3, taken on Dec. 11th, 1895, and Fig. 4)

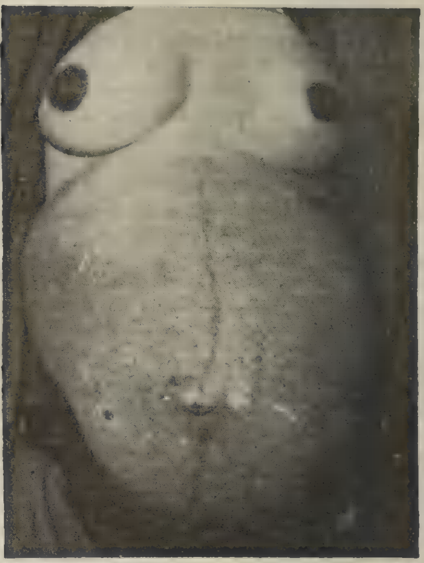

FIG. 3.—Case 12. Showing tumour larger than an adult head on right side of fundus; excessive pigmentation of abdominal wall and areolæ.

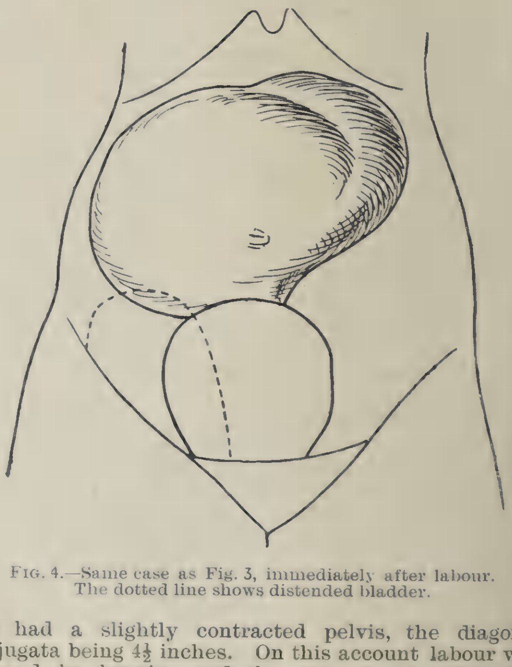

FIG. 4.—Same case as Fig. 3, immediately after labour. The dotted line shows distended bladder.

She had a slightly contracted pelvis, the diagonal conjugata being 4½ inches. On this account labour was induced by bougies and the patient was delivered naturally of a child weighing 8 lb. 1¾ oz. on Dec. 15th. Both mother and child recovered.

PATHOLOGICAL CONDITIONS RESULTING FROM TUMOURS.

In the following case, in which a pedunculated reniform tumour was found at the fourth month, rotation had occurred and had been followed by inflammation and probably sepsis.

CASE 16.—Mrs. S., aged 27, a nullipara, was suddenly seized with pain and inflammation on the left side of the abdomen when four months pregnant. A tumour was found on the left side of the body of the uterus, very tender on examination, and was diagnosed as a twisted dermoid. The tumour was removed by abdominal section on May 20th, 1906. There were no adhesions, but there was a little pus around the tumour, which was greatly congested owing to twisting of its pedicle, which was attached just inside the insertion of the left round ligament. The patient progressed fairly well for two days, then had suppression of urine, secreting only 1½ oz. in 16 hours, the urine containing one-third albumin and bile, and she died on the third day.

A post-mortem examination was not obtained and the tumour was not examined for micro-organisms, but the presence of pus shows that it was probably infected, and I think that death was probably due to septic thrombosis of the ovarian and renal veins. The tumour was a reniform subperitoneal pedunculated myoma weighing 9 oz. and measuring 11½ × 7 × 5 cm. The raw surface of attachment was at the "hilum." The section showed numerous hæmorrhages into the tumour and green patches near the surface. There was a small tag of lymph on the surface (U.C.H., Gyn. Cat. 1911, No. 270).

Intestinal Obstruction.

CASE 18.—M. R., aged 33 (children 0, abortion 0), married four months, in good health, was seen by me on Sept. 21st, 1908. She had last menstruated on July 19th–25th. She had several subperitoneal fibroids, which reached an inch above the umbilicus, and one, as big as an apple, behind the cervix of the uterus, which appeared to be two months pregnant. I advised that she should be carefully watched, and have Cæsarean section at term. Ten days later, in Staffordshire, she had an attack of intestinal obstruction, which, after eight days, was operated upon (supravaginal hysterectomy) by Mr. Spanton (see Proc. Roy. Soc. Med., Obs. and Gyn. Sect., Vol. II., p. 87). It was found that a loop of ileum had become gripped in the sulcus between the large subperitoneal tumours. This sulcus was evident when I saw the patient, and is noted in the diagram taken at the time; but its potential danger was not realised. The patient unfortunately did not recover.

Acute Anteflexion.

Acute anteflexion (resulting from the fixing of the stump of the fundus to the lower abdominal wall) was met with once (Case 21).

CASE 21.—F., aged 24, had the fundus of the uterus, with a fibroid weighing 4 lb. 9 oz., removed on Feb. 26th, 1895 (see Obstet. Soc. Trans., Vol. XL., p. 228), the pedicle being treated extraperitoneally by the serre-nœud and causing a ventro-fixation. The patient having married and become pregnant, the development of the uterus could only take place at the expense of the posterior wall, an acute anteflexion of the pregnant organ resulting. Cæsarean section was performed on Jan. 13th, 1903. The mother made a good recovery; the child also was strong and healthy, but lost its life from hæmorrhage from the cord owing to a badly tied ligature.

Retroversion and Retroflexion.

The next two cases are examples of retroversion and retroflexion of the pregnant myomatous uterus.

CASE 23.—In the second case a fibroid nearly as big as an orange was felt in the pelvis, and above it the retroverted uterus, pregnant nearly two months. The uterus was replaced, and the myoma was then found to be attached to the left corner of the body; it must, therefore, have twisted the uterus through 90°. The pregnancy continued normally and terminated in the birth of a living boy on Jan. 4th, 1920.

CASE 24.—The third case[1] was one of acute retroflexion of the uterus, produced by an adherent fundal myoma (Table C, No. 3). The noteworthy feature of this case was the bulging and thinning of the lower anterior segment, owing to the distension of the uterus having taken place at the expense of the anterior wall. Similar cases have been published by Herman[2] and Varnier and Delbet.[3] Herman's case, treated by Porro's operation, terminated fatally; the other two mothers recovered. In all three cases the death of the child before the operation was undertaken points to the necessity of operating before labour sets in.

Inversion of the Uterus.

CASES 25 and 26.—These were instances of fibroids causing inversion of the uterus after abortion and labour. The tumours were successfully enucleated and the uterus replaced. They are being published in the Proc. Roy. Soc. Med., Obs. and Gyn. Sect., for this year (Vol. XIII.).

Degeneration and Infection of a Fibroid.

CASE 30 (Table B, No. 5).—A. S., aged 42, married, children 0, abortion 1 (December, 1914). She was married in 1904 and had been an in-patient on Dec. 17th, 1914, at U.C.H. for incomplete miscarriage of about nine weeks, brought on by the use of abortefacients. The retained decidua was putrid, and on removing it an intramural myoma as large as an orange was found in the anterior wall of the uterus. Bleeding was profuse, but she recovered well, though the temperature was raised to 100° on three occasions up to the ninth day, and up to 99·6° on the twelfth day; the pulse also varied from 80 to 96. She was advised if she became pregnant again to come to the hospital for Cæsarean section. Accordingly she was admitted to U.C.H. on Feb. 21st, 1917, in good condition and near term. The child was lying obliquely with the head below displaced to the left by the fibroid, which was felt in the lower segment, more on the right side than the left, as a softish tumour as big as a large orange which came down into the pelvic brim. Two other small fibroids were felt in the body. The pelvic measurements were normal. The temperature was 99·4° on admission, but afterwards till the operation only twice reached 99°; the pulse varied between 88 and 104 (on admission 120). Cæsarean section was performed on March 1st, 1917, at 1.30 P.M.

The patient had had slight pains all night and strong pains after midday. The abdomen showed a marked prominence above the pubes, which looked like the distended bladder, but felt thicker walled. It was prominent, but felt soft and fleshy when the uterus contracted; in the intervals between the contractions it felt of the same consistence as the rest of the uterus. The incision did not extend to the fibroid, which was not encroached upon. The child survived. The operation lasted 52 minutes. A submucous myoma as big as a walnut, to which the placenta had been attached and which had been felt on abdominal palpation, was excised. The patient suffered severely from shock, although she had no pain and said she felt well; the pulse and temperature rose to 100; 13½ hours after the operation she had a rigor, with very rapid pulse. On the second day temperature 101°, pulse 120 to 166. She died 60 hours after the operation, obviously from acute sepsis.

Post-mortem.—The abdomen was distended, the abdominal wound healthy. Free fluid present in the peritoneum and a few flakes of lymph. Bowel distended with gas and filmed with pus in places. The deep surface of the wound in the abdominal wall showed early infection. Uterus large and flabby, incision sloughy. The fibroid in the uterine wall felt soft and fluctuating. On opening the preserved uterus the fibroid was found to be of a deep red colour with cavities containing bloody fluid and bubbles of gas in the uterine wall as in gas gangrene. The weather was cold and gas was found in many other tissues of the body. The *Bacillus welchii* was found by Dr. Teale in the tumour.

Tumours Giving Rise to Sepsis After Delivery.

The following are three cases selected out of seven in which submucous tumours were removed after childbirth or miscarriage by enucleation through the os uteri :—

Case 32.—A. C., 35, married, had had one pregnancy resulting in the birth of a living child 11 days before admission on July 21st, 1910. Three days before delivery she began to pass large clots, and on the day before delivery she had a severe attack of hæmorrhage (placenta prævia). Version was performed and a living child delivered. During the following week she had several attacks of shivering with high temperature (104°). I saw her in consultation on the eleventh day, found the uterus large and hard, reaching 8 inches above the pubes. A submucous fibroid, as big as a fist, could be felt on the right side per os. (See Fig. 5.) An offensive bloody discharge was present. Vaginal douches of iodine solution were given, and on July 30th the cervix was dilated by Hegar's dilators and the fingers. The tumour was seized with Doyen's cutting forceps and removed in pieces; the base was very adherent, and in pulling on it the uterus was inverted. This enabled the remains of the tumour to be completely removed. The cavity was then swabbed with iodine solution (ʒi to Oj) and the uterus replaced. Iodoform gauze was packed in the uterus for a few hours. The tumour weighed 1 lb. 3½ oz. It was dull red in colour and in parts was covered with a yellow-green slough. The operation lasted 35 minutes. The temperature, which had varied from 104° to 100° before the operation, reached 100·8°, 100·8°, 101·6°, 103° in the first four days, then gradually fell to normal. The patient left the hospital on August 18th, 1910, and wrote seven months later to say that she was quite well.

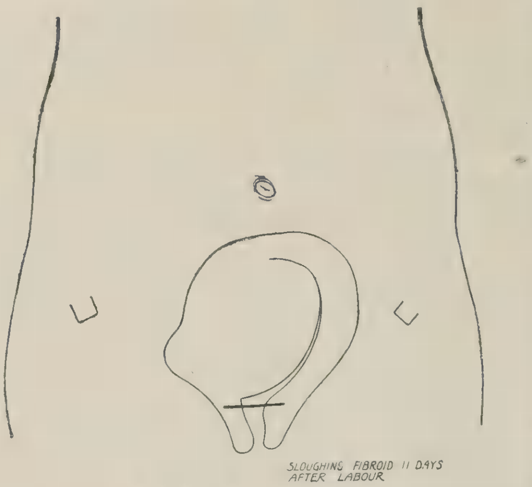

Fig. 5.—Case 32, showing submucous fibroid.

Case 35.—On Oct. 24th, 1898, at 11 p.m., I saw, with Dr. Webb, of Netley, Mrs. F., aged 34, suffering from fever (temperature 100°, pulse 120) and a foul discharge after a miscarriage which had occurred six days previously at the second month. A consultation had been held with local doctors and the finger had been passed into the uterus, the lining of which was smooth. The origin of the foul discharge was not discovered. Under chloroform I introduced my finger and found the smooth condition of the lower uterine canal, but I also felt bulging into the cavity a sessile submucous myoma as big as a walnut; above this, which acted as a ball-valve, some putrid decidua could be touched. I enucleated the myoma, removed a mass of putrid decidua, and washed out the uterus with 1 in 3000 perchloride of mercury solution. The temperature fell to normal, and the patient recovered perfectly. I attended her subsequently in her confinement on Dec. 23rd, 1901, which was quite normal; she also had a second child without any difficulty. She remained in good health till 1917, when she began to lose considerably, and the abdomen increased in size. She became cachectic. I saw her, in consultation with Dr. J. B. Blaikie and Sir Thomas Barlow, on Oct. 5th, 1917. She had a large, fixed, irregular, uterine tumour, nearly filling the abdomen, especially on the left side. She had also pleural effusion and hæmoptysis and other signs of growth in the lungs. From the cachectic condition, the hæmorrhages, and foul discharge it appeared probable that the growth was a uterine sarcoma.

She gradually wasted and died in February, 1918, nearly 20 years after the enucleation of the fibroid.

Case 37.—F. R., aged 31, married at 24; two children, one delivered with forceps 13 months after marriage, and a second at the age of 28, since when menstruation had been profuse and very painful, lasting seven days. She had had bearing down and prolapse of the uterus since the first child was born. Menstruation began at the age of 12, was regular, lasting two to three days, and moderate.

On admission, July 2nd, 1900, she was bleeding profusely, a result of an early miscarriage on the same day. A tumour as large as a goose's egg could be felt attached by a broad base to the left side of the fundus, and above it on the right was some friable decidua. (See Fig. 6.)

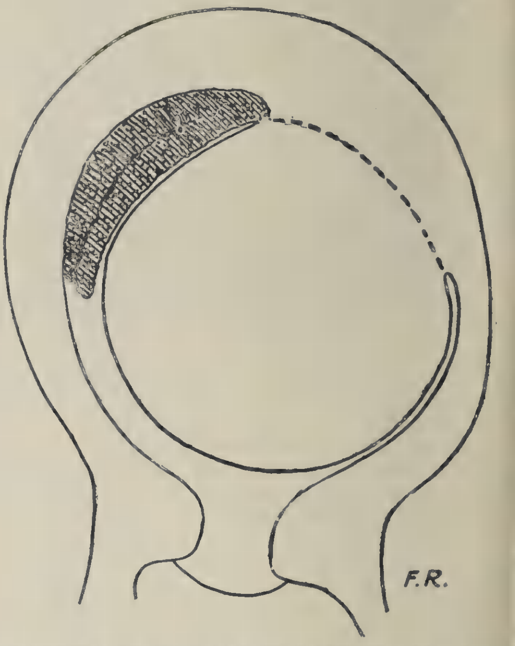

Fig. 6.—Case 37, showing submucous fibroid and decidua.

On July 3rd the tumour was removed by enucleation and the decidua by the finger, and an intra-uterine douche given. The temperature (99·6°) fell practically to normal and remained so till the 14th, when colporrhaphy and perineorrhaphy were performed. The wounds healed well. Fifteen months later, on Oct. 17th, 1901, the patient was delivered of a living child.

Frequency and Age-incidence of Fibroids.

Fibroid tumours complicating pregnancy are quite common, though very divergent opinions have been expressed by eminent obstetricians on this point. Thus, Landau states that in the Charité, amongst 19,052 labours fibroids were found only six times, and Schauta, in 55,311 pregnancies, found only 54 cases of myoma. Pinard, in 13,915 pregnancies, found 84 cases of myoma; and Pozzi, in 12,050 pregnancies, found 83. I have no doubt that the French obstetricians' figures most nearly represent the frequency with which this complication is diagnosed, but necessarily somewhat under-estimate the actual frequency, owing to small or inaccessible tumours escaping observation. I think it may be stated with approximate accuracy that fibroids occur about once in 150 pregnancies.

Bayle, in 1813, wrote that "fibroids scarcely ever appeared before the age of 30 years," but were present in nearly every woman over 40 years who had preserved the physical signs of virginity; and Virchow gave it as his experience that he had examined the corpses of few old virgins in which fibroids were not found, although in many women who had borne children the uterus remained free from them even in extreme old age.

It is now known that fibroids occur, though rarely, before the age of 25 years, and are practically unknown before puberty.[4]

In view of the slow growth of these tumours, of their occasional occurrence at an early age, and their production of severe dysmenorrhœa years before they become manifest clinically, it has been suggested that fibroids are of congenital origin. Essen-Möller has examined the uteri of 20 fœtuses and sucklings, and I have examined the uteri of 100 stillborn girls, without finding any signs of myoma.

Taking the ordinary period of woman's fertility at 30 years, the fact that in the first 10 years she may become pregnant, but is extremely unlikely to have a fibroid, and only in the next 20 years is liable to have both, invalidates most of the voluvoluminous statistics of sterility and abortion in women with fibroid, into which I shall not enter here.[5] There is no doubt that fibroids have a certain influence in causing sterility and abortion, but it is a slight one. Hofmeier is even of opinion that they *increase* fertility, but his statistics are not convincing. On the other hand, there seems to be reason to believe that sterility favours the occurrence of fibroids, and that regular child-bearing and suckling prevent, to some extent, their occurrence (Bayle, Virchow, Pinard).

Effect of Pregnancy on Fibroids.

When a patient with fibroids becomes pregnant the tumours usually increase in size from œdema, hypertrophy, and hyperplasia; the muscle cells become greatly hypertrophied, often swollen, sometimes vacuolated, and occasionally developed into large cells resembling the decidual cells of the endometrium (Gordon Ley). The tumours vary in their development; they usually enlarge. Sometimes no increase is noticeable; occasionally they appear to diminish and their shape is apt to become flatter and their consistence softer than in the unimpregnated organ. They may become more prominent as pregnancy proceeds and alter their shape to clinical examination, owing to change in their location or axes. They may become fixed by impaction in the pelvis or by inflammation resulting from mucous degeneration, necrobiosis, or infection. The necrobiotic fibroid is either grey or pinkish grey or red (usually of a dusky tinge)—the so-called "red degeneration," which is not confined to pregnant uteri, and in my experience is quite as common in the unimpregnated. Degeneration of the fibroid is sometimes accompanied by degeneration of the uterine muscle, which may be more markedly affected than the tumour cells. The degenerated fibroid may be sterile or may be infected, and occasionally suppurates, especially in the puerperium. It would appear that the degenerated or cystic fibroid forms a good cultivating medium for micro-organisms which may be dormant during the pregnancy. I have found an abscess containing a pure culture of streptococci in the centre of a fibroid in a virgin, who gave no clinical sign of its presence except a cachectic appearance. It seems then, that infection of degenerated fibroids may occur from the blood stream; the ordinary route of infection per vaginam often leads to necrosis of submucous tumours, examples of which have been given. Calcification sometimes occurs in fibroids complicating pregnancy, whether the tumours are of uterine or ovarian origin. *After labour* the tumours usually diminish in size and may alter in shape, owing to their rearrangement in the emptied organ. The subperitoneal tumours sometimes do not diminish very markedly in the puerperal month. Their apparent rapid diminution is rather due to increased difficulty of examination. They sometimes undergo very rapid involution, as in Lorain's[6] case, where a tumour, easily felt, as big as the head of an eight-month fœtus at the time of labour, was found post mortem to have diminished on the twenty-second day to the size of a hazel-nut.

As fibroids undoubtedly in some cases undergo great diminution, they are supposed occasionally to disappear after labour. Olshausen's cautious opinion is that it is "not altogether impossible."

In view of the occurrence of rupture of cystic fibroids in the unimpregnated, of which I have seen an example, it is remarkable that there does not appear to be recorded a case of rupture of the pregnant uterus before the onset of labour. Rupture of veins with intraperitoneal hæmorrhage is very rare (Gusserow, Schmorl, L. Meyer, Hamilton, quoted by Troell). The two cases I have met with occurred in nulligravidæ.

Torsion of pedunculated tumours sometimes occurs (Case 16, Table C, No. 2); it is especially liable to happen in the kidney-shaped tumours with pedicle at the hilum (Case 16, and Ribemont-Dessaignes and Grosse's case, quoted by Troell). It is a dangerous accident, 3 out of 21 cases collected by Troell and 1 out of my 3 cases having terminated fatally. This torsion may be transmitted to the uterus and even to the vagina. Troell gives a list of 21 cases of torsion of the pregnant uterus produced by fibroids.

Effects of Fibroids on Pregnancy.

Ectopic pregnancy is rarely met with (Table C, No. 2). In 1886 Gusserow could only find two cases recorded. The specimen from one of these is in the Museum of U.C.H., the case published by Harley in the first volume of the Obstetrical Transactions, which Mr. Lawrence and I, in preparing the Gynæcological Catalogue of U.C.H. Museum (1911), found to be a ruptured uterine horn, and not a ruptured tube, as described. Troell, in 1910, found 49 cases of tubal pregnancy recorded in literature, but Harley's case should be excluded. I am able to add a second specimen from U.C.H. Museum, sent to me by Mr. Bates.

Placenta prævia is said to occur with unusual frequency with uterine fibroids (Case 32). It is probable that hæmorrhages due to submucous fibroids, or to the insertion of the placenta upon them, are sometimes erroneously attributed to placenta prævia. In Case 30 the placenta was situated over a submucous tumour, but gave rise to no hæmorrhage during the pregnancy; the hæmorrhage in such a case may, however, lead to the discovery of the tumour (Case 31).

[6] Gaz. des hôp., 1869, No. 92, p. 361.

While abortion, except in the case of submucous tumours, does not appear to occur with much greater frequency than in normal uteri, both pre-mature and post-mature labour are apt to occur.

Pain or tenderness over the tumour or uterus are frequent symptoms, especially in necrobiotic tumours. The pain is usually easily relieved by rest, light diet, and anodynes. The "unbearable pain," which some authorities have given as a justification for performing hysterectomy in early pregnancy, I have never met with. In cases of torsion, or inflammation, or infection of the tumour, the symptoms are acute, and require prompt surgical interference. Pressure by the tumour on the veins may cause œdema of the lower limbs; albuminuria is not uncommon, and ascites may occur (Table C, No. 2; also Landau's case). Abnormal (especially breech) presentations are frequently met with. The labour is often surprisingly easy in view of the advanced age of many of the patients (Cases 2, 5, 6, 7). Even in the case of tumours encroaching on the brim it is found that the tumour is often drawn out of the way during labour. In some cases forceps may be required for inertia. Retention or incarceration of the placenta or decidua may occur (Cases 31, 35, 37), and post-partum hæmorrhage in cases where the submucous tumours are present may be severe. On the whole, in cases suitable for delivery per vias naturales the labour is often normal, even when the tumours in the upper part of the uterus are quite large. In cases, however, where injudicious attempts are made to deliver the child by forceps or version past tumours even of small size, dangerous bruising of the tumours, or even rupture of the uterus, may occur.

DIAGNOSIS.

The diagnosis of pregnancy and of fibroids sometimes presents difficulties, which are increased when the two are combined. It is more likely that a mistake will be made over the pregnancy than the fibroid. In the first half of pregnancy the great factors in the diagnosis are the suppression of the menses, even if only for a few days, and a uterus larger than it should be and irregular in shape, the irregularities being hard. A uterus may be irregular from pregnancy in one cornu—a lop-sided uterus—but it has the normal consistence; when it contracts and becomes hard it assumes the normal shape. If the pregnancy is advanced to the second or third month the softness of the cervix and body are characteristic, the latter being sometimes best felt per rectum.

In the early months the points to bear in mind are the cessation of menstruation, the rapid growth of the tumour, the consistence of the uterus, and the hard irregularities upon it.

In the second half of pregnancy, when the "certain" signs (heart sounds, parts or movements of the child, and ballottement) are available, difficulties sometimes are met with. In very rare cases, of which I have seen only two or three instances, the uterus remains as hard as a fibroid throughout pregnancy, and is not subject to those periodical relaxations and contractions which ordinarily characterise it. On the other hand, a degenerated fibroid uterus, by its consistence and livid appearance, may closely simulate a pregnant uterus with its contained fœtus, but, of course, the certain signs and the breast changes are absent; menstruation is usually excessive, and I believe the bulging of the anterior lower segment, which is sometimes seen in the case of fibroids, is never met with in normal pregnancy, though it may be found extremely marked in retroflexion of the pregnant uterus, produced by fibroid of the fundus adherent in the pelvis (Case 24). When there are irregularities on the surface of the pregnant uterus the diagnosis is simplified; the prominences are hard, the pregnant uterus soft and contractile; the fibroids do not alter their position, as parts of the fœtus do, and they may become more marked during uterine contractions, which obscure the fœtal parts; at most, the tumours have a slight mobility, but return to the same position even when repeatedly examined. Large subperitoneal or intramural growths, or small multiple growths, may render the palpation of the fœtus difficult till the pregnancy is somewhat advanced.

If the fibroids are degenerated they may feel softer than the rest of the uterus when the latter contracts (Case 30). When cystic and of large size they are difficult to distinguish from ovarian tumours (Case 15); the same difficulty may occur in diagnosing twisted fibroids in the acute stage, though the hardness will be in favour of uterine fibroid, and the age of the patient may assist the diagnosis.

In all cases of difficulty, especially with impacted or inflamed tumours, examination under anæsthesia is of the greatest value. I need only allude to the resemblance of a horn of a double uterus to a fibroid, for which it has been mistaken, and has led to the sacrifice of the uterus when excision or even replacement of the horn would have sufficed.

Diagnosis in the Puerperium.

After the birth of the child the diagnosis of subperitoneal and intramural tumours is usually easy, owing to the lax state of the abdominal wall and the smaller size of the uterus. Submucous tumours may be overlooked, unless they give rise to hæmorrhage or to fever from necrosis or gangrene. If the uterus is large and hard in the puerperium a submucous fibroid should be suspected and the uterus should be explored. Fever may arise either from retention of the products of conception or from infection of the tumour, especially if it has undergone degeneration. A tender subperitoneal tumour in the puerperium associated with fever will suggest infection. I have known a large intramural tumour mistaken for a second twin; in that case the hardness of the tumour and the absence of signs of the fœtus rendered the diagnosis easy, but if the tumours were degenerated considerable difficulty might arise, which would be overcome by exploration through the cervix.

A fibroid impacted in the pelvis, especially if it is cystic (Case 27), may closely resemble an ovarian cyst, and a subperitoneal fibroid, after abortion, may resemble a tubal mole, from which its hardness distinguishes it. Inversion of the uterus is met with, usually some weeks or months after labour or abortion. In addition to the usual signs of inversion, there will be a tumour, usually separated by a groove and distinguishable from the uterus by its harder consistence. A case of mine in which these two points of distinction were absent is, so far as I know, unique.[7]

PROGNOSIS AND TREATMENT.

The prognosis is, in the great majority of cases' good when the patients are attended with judgment and careful regard for asepsis. The three fatal cases here published, which are all that I have met with, are examples of dangers which sometimes arise. The first death (Case 18) from intestinal obstruction, due to nipping of the ileum between two subperitoneal fibroids, is a very rare accident, of which I have not been able to find another example. The other two deaths (Cases 16 and 30) suggest the necessity of bacteriological examination of the tumour before resorting to conservative abdominal operations.

The great majority of cases require only careful supervision during pregnancy, periodical examination of the urine, and rest, mild aperients, and anodynes if the tumours become painful. Induction of abortion and premature labour and forcible delivery past obstructing tumours are contraindicated. Forceps may be required for inertia, but should never be used to overcome resistance caused by tumours. Craniotomy and embryotomy are called for only in cases where the fœtus is dead and the mother not infected. Polypi and pedunculated subperitoneal tumours should be removed.

Vaginal myomectomy may be required for cervical fibroids, but should not be performed for retrocervical tumours.

Abdominal myomectomy is rarely needed, and usually only for very large or twisted or necrobiotic tumours. It not infrequently leads to abortion and to hysterectomy in order to stop the hæmorrhage from the bed of the tumour, and it often fails to remove all the tumours present in the uterus. Before performing myomectomy, as also before conservative Cæsarean section, the tumour should be examined bacteriologically, and if it is infected the whole uterus should be removed.

Hysterectomy during early pregnancy, in the absence of hæmorrhage or infection, is rarely called for. Myomectomy and hysterectomy in early pregnancy are frequently performed by some gynæcologists.

Thus, T. Landau[8]—who has written an important monograph on the subject of myoma and pregnancy, illustrated by many fine plates of fibroid uteri

TABLE A.—*Author's Cases of Pregnancy Complicated by Fibroids Treated by Abdominal Myomectomy.*

* Induced at 6½ months. † Dead before operation.

taining little fœtuses sacrificed in some cases, it appears to me, unnecessarily by the operation of hysterectomy—gives a list of 11 cases of abdominal myomectomy during pregnancy, apparently operated upon by his brother and himself. All the patients recovered and only one aborted. A careful reading of the history of the cases leaves a doubt as to whether the operation was in all necessary or advisable.

Landau also gives a list of 19 cases in which hysterectomy was performed in the early months of pregnancy; in some of the cases the pregnancy was not diagnosed before the operation; in others, what was intended to be a myomectomy terminated in hysterectomy; one of the mothers died; the others were, of course, sterilised, and the children sacrificed. The practice of hysterectomy in the early months of pregnancy is, in my opinion, much too common both abroad and in this country; I have never found it necessary.

In Table A are given my cases of abdominal myomectomy during pregnancy. Of the mothers, four recovered and one died (undelivered) at the fourth month of pregnancy. In No. 1 the child was dead at the time of the operation. In No. 2 abortion occurred before the operation. In Nos. 4 and 5, operated on at the eleventh and sixth week, the pregnancy continued and living children were born.

Every endeavour should be made to enable pregnancy to be carried on until the child is viable, when a conservative or radical Cæsarean section may be performed.

Conservative Cæsarean Section (Table B).

This is rarely indicated by the fibroids alone, but may be performed when fibroids are associated with contracted pelvis or malpresentations of the child, especially in elderly primiparæ. In the case of a single myoma it might be possible to remove the myoma and child through the same incision. Landau, who removed the uterus 19 times during early pregnancy, does not record a case of conservative Cæsarean section.

My five cases are given in Table B. In all contraction of the pelvis and the presence of fibroids were the indications for the operation. The five children survived; one mother died owing to my failure to discover the infection of the tumour. The case should have been treated by total abdominal hysterectomy.

Cæsarean Section Followed by Abdominal Hysterectomy (Table C).

Landau performed the operation in two cases only; the mothers and one child recovered; of the other child it is stated that it was a well-developed boy, but whether it survived or not is not mentioned. My six cases are given in Table C. All the mothers recovered, and all the children survived except one, which was dead before the operation was performed. Total hysterectomy, which was performed in five of the cases, is, in my opinion, preferable to amputation in pregnant as in non-pregnant cases, especially as it provides drainag and removes the possibly infected cervix.

Troell gives a list of 20 cases (including 2 of mine) operated on since 1900, with 2 deaths. I am able to add 3 more cases (Table C, Nos. 4, 5, 6 making 23 cases with 2 deaths.

In the puerperium vaginal myomectomy is usuall the best treatment for submucous tumours, eve when they are infected or invert the uterus. It should usually be tried before resorting to hysterectomy, which I have never found to be necessary. In infected subperitoneal or intramural tumours total abdominal hysterectomy should be performed.

Presidential Address

ON

SURGERY DURING THE WAR.

Delivered before the Medical Society of London.

BY V. WARREN LOW, C.B., M.D.LOND., F.R.C.S.ENG.,
SURGEON TO ST. MARY'S HOSPITAL, LONDON, W.

GENTLEMEN,—He would indeed be singularly wanting in imagination who could occupy this chair without feeling a grave sense of responsibility at being entrusted, even for a year, with the guidance of the affairs of this old society. Among my predecessors have been many able men, some very eminent and some, I am glad to think, very ordinary. Genius, while it adorns such a position as this, is not really essential. All have, however, resembled each other in doing their best in the interests of the Medical Society, and in this it will be my humble endeavour to imitate them.

I am particularly lost in admiration of my four immediate predecessors, who, during the chaos of the last five years, have maintained, and at times have even excelled, the high standard of interest which has ever been the feature of the meetings of the Medical Society of London. This, I think I can say without fear of contradiction, has been a feat unique in London, and, so far as I can judge, in the provinces. That this has been due to the energy of our Presidents, of our secretaries, and of our registrar is undeniable, but I would also suggest that the peculiarly catholic composition of the meetings of this society may also have been a contributory factor. Here practitioners of medicine in the widest sense of the term meet to discuss problems of mutual interest, and there is no anomaly in the Medical Society having as its President a laryngologist or a surgeon. Discussions at meetings composed entirely of physicians, or entirely of surgeons, or entirely of men interested in one or other of the specialties, tend to become highly technical, and this tendency often develops to such an extent that further fission takes place and coteries are formed to discuss still more technicalities. In a profession so highly technical as ours has become, there can be no denying that such discussions are most necessary, but it must also be remembered that we are all practitioners of medicine in the broad sense of the term, and the side-lights that may be cast on a surgical problem by physicians, or by those interested in other specialties, or vice versa, may do much to preserve that sense of perspective, of which the loss so often mars an otherwise brilliant conception.

I have dwelt, perhaps you may think unnecessarily, on what is an obvious truth, but there are times when to emphasise a point one must labour the obvious. The point I wish to emphasise here is that in this new world, on the threshold of which we are said to be standing, there is a place—there is a need—for this old Medical Society of London. I know of no society which more closely links together all those within its folds, whether they be general practitioners, in the modern sense of the term, physicians, surgeons, or those interested in the various specialties. Probably no body has retained for 150 years so exactly the character intended for it by its founder as has this society retained the impress left on it by Dr. Lettsom. It is for us to see that this heritage survives the present taste for reconstruction. Reconstruction is in the air, it crops up in the most unlikely places. It has not altogether passed us by. An attempt to reconstruct us on bisexual lines, which sent a shiver down the backs of some of our sturdiest, failed, to be followed by a more successful attempt to reconstruct our financial position. Our subscription after being 1 guinea for 146 years has now been doubled—that, alas! is one of the peculiarities of this new world, everything is more expensive. How necessary was this is well set forth in the report of our treasurer, Dr. Mitchell Bruce, to whom this society owes a deep debt of gratitude. Possibly this increased subscription may be responsible for some resignations, but these will be due as probably to the general post in the profession, which is inevitable as the result of a five years' war. It should be our endeavour to see that each of these vacancies is filled up twice over, and that this old society is once more launched forth on another century of usefulness. In this connexion I would remind the Fellows that we have lost by death during the last 12 months 16 of our number. Three of these were old Presidents—Mr. Brudenell Carter, Dr. Frederick Roberts, and Sir William Dalby—all three joined the society in the early "seventies." The society has sustained a serious loss in the untimely death of Dr. Leonard Guthrie, an old colleague of mine, as secretary and later a Vice-President. I had looked forward to seeing Dr. Guthrie in this chair, one of our most distinguished Presidents. We also deplore the loss of Dr. Cahill, Dr. Lovell Drage, Mr. Betham Robinson, Dr. Percy Lush, Dr. Nias, and Dr. Guthrie Rankin, all of whom had served the society on the Council.

THE TREATMENT OF CONTAMINATED WOUNDS.

During the war the papers and discussions were, with few exceptions, on military medicine, surgery, or hygiene, and a study of the last four volumes of the Transactions is to epitomise the various problems that have had to be faced during the last five years. Many of these problems fortunately may not have to be faced again, and much that has been learnt may be cast into "the limbo of half-forgotten things." But from it all will emerge observations, technique, and conceptions which will, I believe, have a far-reaching influence on medicine and surgery, and will occupy the discussions of this and kindred societies for many sessions. It is an interesting exercise to speculate on the value of the various legacies left us by the war, and it is my intention to endeavour to appraise the value of a few of our newly acquired surgical assets as tested by the needs of a civilian population.

In the summer and autumn of 1914 surgeons were made to realise that their influence over the course of a septic wound was remarkably slight. Enormous progress had been made in the prevention of sepsis; so much so that sepsis in any marked degree was seldom seen in ordinary operation wounds or in accidental wounds which had received prompt treatment. Owing to their comparative rarity it was not perhaps completely realised that wounds in which sepsis was well established were practically left to Nature, with the assistance, possibly, of drainage and protection. In Flanders in 1914 such self-deception became no longer possible; practically every wound was septic, and surgery was comparatively helpless. Surgeons who had hitherto relied on extreme cleanliness fled to chemical antiseptics, and the advocates of antiseptics discarded their old favourites for each new germ-killer which the ingenuity of chemists could suggest. It was about this time that a friend of mine who was doing a good deal of surgery in one of the war zones told me that he derived much assistance and stimulation from reading Guthrie's experiences in the Peninsular War.

Gradually, however, we came back to first principles. It was slowly realised that a contaminated wound is not at first an infected wound, and that the careful excision of contaminated and devitalised tissues was the most important measure of antisepsis. It was also about this period emphasised, though it had long been realised, that bacteriological and surgical asepsis do not coincide, and that a wound is capable of clean healing though in it the bacteriologist might still be able to demonstrate germs. Consequently many of these wounds were sewn up at once; while others were watched for a few days, and, if still uninfected, underwent a secondary suture, with enormous advantage in saving of time and suffering to the wounded men. In the summer of 1915 I was excising wounds in the Dardanelles, but I had not realised the truth of the second proposition and I spoilt my results by excessive drainage, and thereby facilitated subsequent infection.

But, though surgery had thus improved the treatment of the wounded man, and had again proclaimed the eternal truth that the healing of wounds lies in the prevention of sepsis, yet we had not yet learnt how successfully to treat a septic wound when once infection was well established, and this is a question we may well ask ourselves now. The nearest approach to it, in my opinion, is the method of wound treatment known under the name of the Carrel-Dakin. Hypochlorite of soda is not a modern innovation, as it was discovered in 1788, and by its aid Louis XVIII. was, I understand, embalmed. I suppose most surgeons of my age have often employed the liquor sodæ chlorinatæ of the Pharmacopœia for stinking wounds.

Now solutions of hypochlorite are undoubtedly irritating, a quality usually ascribed to the free chlorine, but which was shown by Dakin to be due to free alkalies. By providing for the neutralisation of these alkalies Dakin has provided us with a very serviceable antiseptic. The Carrel-Dakin treatment, however, carries us further than this. Hypochlorite of soda rapidly disappears when in contact with the secretions of the wound. It is conceivable that, in this respect, it resembles other antiseptics; in order, therefore, to obtain its proper effect it should be instilled into wounds continuously or at short intervals. There is an overwhelming mass of evidence from our various war zones as to the efficacy of this method of treatment, and to this I must add my own, though for some time I was undecided between this and the physiological treatment by hypertonic salt solution, as suggested by my colleague, Sir Almroth Wright. Perhaps almost the best testimonial the Carrel-Dakin treatment has had was from my colleague, Alexander Fleming, who, while admitting the efficacy of the treatment, ascribes its success rather to its physiological than to its bacteriological action. Whether this be so or no is probably not yet capable of scientific proof, but every surgeon would welcome some means of controlling and stimulating the physiological defences of the body against sepsis, and it is to such men as Sir Almroth Wright and his co-workers that we shall have to look for help in this direction.

One variety of sepsis has, however, lost some of its terrors. Whatever else this war has achieved it has certainly thoroughly stabilised the reputation of tetanus antitoxin as a prophylactic against tetanus, if administered at a reasonable interval after the infliction of the wound. In fact, its very success has created a new disease, and the existence of localised tetanus of the limbs has now been firmly established. In looking for these cases one has also had opportunities of realising the extraordinary number of cases of hysterical spasm of the extremities which may result from wounds, in some cases even following local tetanus. I cannot do better than to refer you to a most interesting paper by Dr. A. F. Hurst in the *British Journal of Surgery*, in which an account is given of a number of these cases and of their successful treatment, not by psycho-analysis nor by hypnosis, but by explanation, persuasion, and re-education.

MODERN VIEW ON SHOCK.

Never, perhaps, have experimental physiologists and clinicians had a more fruitful field and a better opportunity of research than have the Special Investigation Committee appointed by the Medical Research Committee to undertake the coördination of inquiries into surgical shock and allied conditions, and the green pamphlets of the Medical Research Committee are worthy of and require the most careful consideration of every surgeon.

In 1914 the current view of the cause of the failure of the circulation in shock was that enunciated by Crile, that it was due to exhaustion of the vaso-motor centres by excessive sensory stimulation, and that the blood accumulated in the great veins of the splanchnic area. It was always a stumbling block to this view that practical surgeons could never be certain of this accumulation of blood when performing hurried laparotomies on shocked patients. New conceptions now hold the field, and while excessive sensory stimulations may be a contributing factor, the most potent agents in the reduction of blood pressure are probably toxic substances produced by the damage to the tissues, particularly to muscles. The blood stagnates, not in the splanchnic area, but in the capillary network, owing to the general loss of the normal tone of the capillary walls. There is much experimental work and clinical observation in favour of these views, and the shock produced in cats by the injection of the substance histamine is a very suggestive analogy.

By a very ingenious method of injecting a non-toxic, non-diffusible, dye-substance—vital red—into the blood stream and estimating its dilution N. M. Keith has shown that the shocked man has a reduced blood volume, and that his power of recovery is largely connected with the power of the circulation to take up fluids from the tissues or to retain added fluids. The reduced blood volume in simple shock is probably due to the transudation of plasma through the abnormally permeable capillary walls. It is suggested that these effects are produced not so much by the exhaustion of the nervous control as by the presence in the circulation of certain cleavage products of protein acting as chemical messengers or hormones. To use a simile of Professor A. Keith's, there is not only a telegraphic and telephonic inter-communication via the nerve fibres in the body, but there is also a postal system, and the tissues are influenced by missives arriving in the blood stream. The presence of adrenalin in the circulating blood of frightened cats, as shown by Cannon and also by Elliott, is a hint that shock from emotional stress has a similar causation. These considerations open up another chapter in the study of the modern theory of hormones, substances which Professor Keith has suggested are possibly even responsible for our racial characteristics. There is nothing startlingly new in the treatment of shock, but our knowledge has become more systematised and we have shed certain superfluities. Rest and warmth still occupy the chief place; stimulants and drugs, except small doses of morphia, have been discarded. Gas and oxygen are even more firmly established as the anæsthetic of choice where local anæsthesia is not convenient. Most important is the free administration of fluids by mouth or by rectum, or, if the shock be more profound, intravenously. Here, however, is a difference. Normal saline, whether subcutaneously or intravenously, has been discarded, and for it has been substituted either Bayliss's gum saline solution or blood. There is still some controversy as to which of these two is the more efficacious, and it is possible that the fact that a large proportion of the shock cases in France were also cases of hæmorrhage may have given an undue advantage to the transfusion of blood. Robertson's technique of indirect transfusion of citrated blood was that usually employed, and will be a useful addition to the equipment of our operating theatres. It must, however, be borne in mind that as operating surgeons in civil life we are, perhaps, more concerned in the prevention of shock than in its cure; but in connexion with the large industrial centres resuscitation wards will be as necessary as they were in the casualty clearing stations in France, only let us hope they will not be so busily employed.

The excision of the contaminated and devitalised tissues of the wound wall, as the prime measure of antisepsis, influenced the surgery of every part of the body. In head injuries Cushing and his followers excised the scalp wound and also the wound of the skull en bloc, sucked out the debris in the wound track through a soft catheter, and occasionally successfully removed the foreign body by means of a small iron rod (usually a French wire nail) attached to a powerful magnet. What, perhaps, is a useful fact for future guidance is that the majority of these operations were performed under novocain.

ABDOMINAL SURGERY IN TWO WARS.

Abdominal surgery, after suffering somewhat from the conservatism of the South African War, was resuscitated by the efforts of, among others, an old secretary of this society, Sir Cuthbert Wallace, and many feet of injured intestine were successfully excised by many operators from patients who would otherwise have died miserably. Perforated viscera were mended and bleeding vessels were ligatured. That this was possible was due largely to the peculiar immobility of the fighting zone in the late war, and also to the fact that the army adopted, what has always been a feature of civil hospitals —namely, the principle of team-work. The term "team" in this connexion may be new. I think in London the expression "firm" was not uncommon, but under whatever title the principle was well established that a surgeon and his assistants should be associated together for at least some months, and in many cases longer. This is what was attained in the casualty clearing stations in France, but on a scale hitherto undreamt of in civil or military experience, and it says much for the organising energy of those who initiated it. In the Dardanelles, owing to the peculiar nature of the front, we were able to bring our hospital ships up even closer behind the fighting line, and I have opened the abdomen of a man in a first-class theatre with the aid of sisters and nurses within three-quarters of an hour of having seen him hit by a shell.

I should like to pause for a moment here to say one word in defence of the conservatism of the South African War. That was essentially a war of movement. We usually slept some 10 to 15 or 20 miles from where we were in the morning. Transport difficulties debarred us from tents, beds, and clean clothes for the wounded, our nearest fixed hospitals were often several days behind us, even with the fleetest transport we possessed. There was no fuel for sterilisation, and often very little water. Anything like an abdominal operation was out of the question. Human nature is extraordinarily adaptive, and gradually our beliefs adapted themselves to our environment, and we became firmly, and I think honestly, convinced that non-interference was the wisest course in bullet wounds of the abdomen; it must be borne in mind that shell wounds were extremely rare.

In addition, we were occasionally meeting cases where this belief was obviously justified. In looking through an old note-book I see that in the fighting outside Pretoria in June, 1900, I picked up and looked after a gunner with a bullet wound through the body, the entrance being in the left loin about 1½ in. from the middle line and below the twelfth rib, while the wound of exit was 2 in. to the left of the middle line, and about 1½ in. above the umbilicus. This man apparently never suffered the least inconvenience after the initial pang of the wound, and a week later his only complaint was of the prolonged starvation to which I had subjected him.

During the latter part of the war abdominal injuries were treated as they would be treated in the civil hospitals of any big city, and it was realised that even a blank exploration was better than leaving a doubtful case. The only novelty was its adaptation to war conditions, and possibly the chief legacy it has left us is a number of enthusiastic young surgeons thoroughly well trained in the technique of abdominal surgery.

NEW LIGHT ON SURGICAL PROBLEMS.

It is, perhaps, when we come to the application of the principle of excision of the wound to injuries of the chest that we see the most startling innovations. The free opening of the chest in cases of hæmothorax and in wounds of the lungs produced by shells, with the immediate and tight closure of the wound, as advocated and practised by Pierre Duval and introduced into our hospitals by Mr. George Gask, another old secretary of this society, in addition to saving many lives abroad will, I think, be a prelude to another chapter in thoracic surgery. It has, at least, taught us that no special pressure chamber installation is necessary for lung surgery, and that a total pneumothorax, so far from being a source of danger, actually places the lung under the best possible conditions for surgical manipulation. I faintly realised this so far back as 1904, when, while endeavouring to remove a growth, which I thought was confined to a rib, I found myself in the course of the operation with a widely opened thorax and a collapsed lung, from which I had removed a portion of the lower lobe. My astonishment at what I had done was only equalled by my surprise at the way in which the lung responded to the ordinary measures of hæmostasis, and at the comparatively slight disturbance of the patient, who made an easy recovery, but, unfortunately, later succumbed to a recurrence of the growth. Again in this class of surgery has the superiority of regional and local over inhalation anæsthesia been emphasised, and, although I realise that many surgeons for some years have made use of local anæsthesia for excision of ribs in opening empyemata, I think now that the practice will become more general.

Seldom has human ingenuity been subjected to a more severe test, and seldom has there been a better response than in the treatment of fractures during the last five years. It would be beyond my powers to appraise the value of all the various splints which have been devised for the treatment of almost every variety of fracture, and which will, I trust, have a profound influence on the future treatment of fractures in civil hospitals. There will be, I venture to predict, a complete emancipation from the somewhat rigid lines on which these injuries have hitherto been treated; and there will also be, I think, a revolt against the tyranny of conventional splints, and, may I add, of instrument makers.

Until 1914 there had been little encouragement for the busy hospital surgeon who was gifted with a mechanical mind to experiment much in splints. During the war such a man has had every opportunity. To those of us who have had the care of military cases at home those voluntary associations known under such names as war stores or depôts, working in conjunction with the Red Cross, have been the greatest boon. Educated men and women, as a labour of love, have shown the greatest skill and untiring patience in planning splints on the specifications of surgeons to meet the peculiar needs of particular cases. I cannot imagine a more practical form of charity than the continuance, in a modified form, of some such bodies as these to supply the needs of the civil hospitals. Every hospital should have, as some already do, a man sufficiently skilled as a metal worker and carpenter who could himself make, under the direction of the surgeons, a proportion of the splints and mechanical contrivances required in the hospital. Whether this would be an economy or not I am not in a position to say, but I am convinced it would add to the efficiency of the work done in this department.

Compound fractures leave behind them an aftermath of septic sinuses and bone cavities; these will provide occupation and food for thought for a generation of surgeons. I am not convinced that we have yet found any royal road to success in the treatment of these cases, a subject more suitable for a general discussion by the society than for any ex cathedra statements from this chair.

Septic injuries to joints emphasised the extraordinary difficulty we have most of us always experienced in dealing with these cases, and also confirmed the already expressed suspicion that the conventional drainage of such a joint as the knee-joint was not always the surest road to success. In addition to an enormous legacy of stiff and deformed joints the war has left us a number of flail joints as the result of rather extensive excisions, and with these it is a difficult problem to know best how to deal.

Almost as plentiful as fractures were injuries to nerves, and a large amount of experience in dealing with these cases has been accumulated, although, unfortunately, it is not altogether in unison. Among the many subjects for discussion is the best method for bridging the gap, in the continuity of a nerve, too wide for suture of the divided ends. Nerve transplantation, or grafting, as it is often called, and double lateral implantation into a neighbouring nerve, have each their advocates and their critics. Some would even shorten the limb (in the upper extremity) by excision of a portion of bone in order to bring the nerve ends together, while others prefer to leave the nerve alone and to rely on transplanting unaffected muscles to do the work of those paralysed. I am personally in favour of nerve transplantation, using nerve-grafts of the same size as the injured nerves, and these can only be obtained from recently amputated limbs or from amputation stumps. The difficulty, however, in speaking with much authority on such a subject is increased by the length of time that must elapse before one can judge the results, and hitherto by one's inability to keep in touch with demobilised and scattered soldiers. I look forward in the future to an exhibition of results of the various methods of treatment some two or three years after the event, and I have no doubt that the experience gained in this war will do much to clarify our views on the solution of what has always been a difficult problem.

I am standing, however, on common ground when I impress on those of us who are responsible for medical education the importance of exacting from students an accurate knowledge of peripheral nerve distribution and of muscular function—points on which, speaking as an examiner, I am inclined to think sufficient emphasis has not hitherto been laid.

CONCLUSION.

I have touched lightly on a few of the surgical problems which have been ventilated and illuminated by the events of the last five years, and in doing so I have employed the time which I consider should be occupied by the president in introducing himself to the society, but I have scarcely dealt with a tithe of the subject. Plastic surgery, bone grafting, and the surgery of the vascular system each require a chapter to themselves, so extensively has our knowledge grown on these subjects. When one realises this and remembers that general medicine, hygiene, and tropical medicine have all also accumulated masses of new facts and experiences, it is justifiable to believe that we are on the threshold of a new epoch in medicine and that an enormous impetus will be given to the discussions of societies such as this, as this new material becomes digested and classified.

The war has left us a legacy of disease and disabilities; it has also given us a riper experience and a wider knowledge. It is for us to see that the Medical Society of London shows the same activity in the collection and distribution of this new knowledge as it has done for the past century and a half.

GAS POISONING.[1]

BY SIR WILMOT P. HERRINGHAM, K.C.M.G., C.B., M.D., F.R.C.P. LOND.,

PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL; LATE MAJOR-GENERAL, A.M.S.

ON April 23rd, 1915, Bowlby and I were at Bailleul when a rumour reached us that something extraordinary had happened in the north. We drove at once to Poperinghe and learnt that the French Colonial Corps that held the line to our left from somewhere about Langemarck to Dixmude, where they joined the Belgians, had retreated the previous night, part of them through Poperinghe itself. We drove out to Vlamertinghe, where we found a Canadian F.A. and passed on the way the Northumbrian division going up. One battalion were playing football by the side of the road. At Vlamertinghe we could get no certain news except that the French had fled, and that the Canadians had met the advancing Germans about Pilkem and had held them there. But in the field ambulance I found three Algerian soldiers from whom I made out that the Germans had pumped some fluid out of pipes, had set light to it, and that a dense cloud of some kind had come down upon them which choked them. While we were there a man was brought in whose clothes had a curious smell, and in about five minutes every man in the room had to go out into the open air because our eyes watered so that we could not see. That was my first introduction to Cl and to the tear gas, xylyl bromide.

I need not remind you how the retreat of the French Colonial troops let the Germans in on our left, and eventually obliged us to retire on the Ypres salient, nor how terribly we suffered in consequence. It was about three days later that the same thing happened to our own troops. It was a little lower down the line and the cases were brought in to Bailleul. After that attacks were repeated all through the summer, but as means of protection improved had much less result.

The gas from April to the autumn was Cl. During the winter phosgene began to be used, and in 1916 it was sent over in shells which exploded differently from H.E. shells and could easily be distinguished from them until the enemy began to mix them in a bombardment. We were the first to send over the gas in projectors, which enabled large quantities to be concentrated on a small area and destroyed a great many Germans.

The action of these two gases was much the same. When I first saw the cases in April and found that they turned blue quite early, and, secondly, that they could not be made red again by oxygen, I thought that the hæmoglobin must be in some way changed into methæmoglobin. I had no experience of cyanosis from reduced Hgb which could not be removed by oxygen. However, Macnee and Dr. Haldane both showed that there was nothing but reduced Hgb in the blood.

The men were in great distress, breathing very rapidly, coughing continually, bringing up a yellow, thin, watery frothy fluid, and occasionally vomiting. The cyanosis persisted in spite of oxygen inhalation given as we then gave it, and eventually a large number—10 per cent. of all brought in—died of suffocation.

We gradually recognised three classes. (*a*) The severest of all, which were either collapsed from the first or became collapsed after a day or two. When collapse was present the colour was an ashy grey, the breathing was rapid and shallow, and the pulse was very small. These cases died rapidly. (*b*) Those which were severely affected, but were purple in colour and had a full though rapid pulse. Some of these became progressively worse and eventually became collapsed and grey, and then died. Others, if carefully treated, recovered. (*c*) Slighter cases which showed little cyanosis or none, and only had a slight cough.

Post-mortem examination showed laryngitis, enormous œdema of lungs, emphysema on edge of lung, and air under pleura.

Haldane and other experimenters in England explained the whole course of events, and the various degrees of severity, as all due to but one cause, the want of oxygen in the blood due to the wall of œdema interposed between the air and the blood-vessels. It seemed to me probable that there was also, in those cases which collapsed at once, some other more direct action on the heart.

We rapidly learnt also that exertion, sometimes even very slight exertion, made the patients worse. Thus men who had been comfortable while lying became rapidly worse and sometimes died suddenly if they walked or sat about. The extra amount of oxygen needed in the exertion could not be supplied, and the results showed at once.

At first our treatment consisted in oxygen inefficiently administered and stimulant expectorants, almost always amm. carb. The relief produced by natural vomiting led us to give emetics. But we soon found that these exhausted the patient more than they relieved him. Atropin was tried with the idea that it would diminish the effusion of fluid, but it had no effect.

There was considerable controversy over the effect of bleeding. It was reported to have been of good effect, and in especial in a batch of 100 Seaforths, who were gassed on their way down from the front line in front of Arras. But it takes many clinical observations to establish any rule of treatment, and meanwhile the experiments in England were opposed to bleeding. I urged it always, but it was not till a second series of experiments showed that bleeding was of use that I could get it adopted. It was of no use for cases of collapse, and, indeed, made them worse, and it was not needed for slight cases. It was of use in the cases of cyanosis with a full pulse.

But the main remedy was undoubtedly oxygen. At first we gave it as we had given it to cases of pneumonia at home. This was of little use; we moulded masks out of gutta and celluloid, and gradually gave the gas with less waste and more continuously, and to several at a time by means of apparatus made out of petrol tins and gas pipes.

But gradually we received supplies of Haldane's apparatus, which was fixed straight on to the cylinder of oxygen, and contained (1) a transformer, reducing the pressure to moderate limits, (2) a distributer by which four patients could be fed at a time, and the number of litres per minute given to each checked. This, when earnestly and faithfully employed, was very efficacious. I have seen men in whom the stoppage of oxygen for any five minutes during the first 48 hours turned them blue again, eventually recover.

After the war was over and I had come home I learnt that a chemist employed in some industry in the north who was in the habit of going to Germany periodically had in 1909 come upon a party of soldiers evidently experimenting with some poisonous gas on a herd of sheep, many of which were dying or dead. He was warned off so quickly that he had no opportunity to see any details, and thought no more of it.

Our people were quite unprepared for anything of the kind. It created a great panic at headquarters, and it both frightened and at the same time exasperated the soldiers. For some time after that we had frequent alarms that some new method was contemplated, and, among others, the oddest was the news that "quebracho" was to be employed. There was nothing to be made of quebracho in any books available, and it did not seem likely to be dangerous, but it was firmly believed in for some time.

The authorities, at the head of whom was Colonel Cummins, immediately set to work to devise protection. The flannel rags were succeeded by respirators chemically treated, and then by cloth helmets, which were improved as time went on. But it was not till the autumn that these could be provided in sufficient numbers. A plant was set up in France for renewing the chemical soaking, but the chief weakness of the helmets was the gelatin or talc eye-piece, which was often broken and thus made the helmet useless. Ultimately, about two years later, the helmet was replaced by the box respirator, which was a very efficient protector.

On the night of July 13th, 1917, the Germans for the first time employed di-chlor-ethyl-sulphide, or mustard gas, on the front north of Ypres, and a fortnight later in the Nieuport sector. In each case between 3000 and 4000 casualties occurred. I was with G.H.Q. at Hesdin at the time, but got to the Proven area where the first set of cases were admitted a day or two later, saw a large number of cases and a few post-mortems. In a field ambulance north of Furnes I saw a large number of the second batch while they were still coming in.

They were of a totally different character from the earlier cases of Cl or phosgene poisoning. It had three main actions: the first causing violent conjunctivitis with swelling of the lids; another scorching the whole of the air-passages so far as it penetrated; and the third inflaming the skin, and producing, even without previous inflammation, large areas of brown pigmentation. It was said by some that the parts of the skin chiefly affected were those in which there are sebaceous glands.

The effect upon the eyes was such that the men were practically blinded. In the hospitals you might see what Mr. Sargent so well represents in his picture now in the Academy, strings of men led by one who could see, groping their way about the camp. The skin where affected was of a fiery red, and many men were sent in as cases of scarlatina. In some cases the burns were so severe as to cause death. They were worst on the buttocks and about the genitals where the skin was sweaty. The most dangerous lesion was in the air-passages. The nose, fauces, larynx, and trachea were often so badly scorched that the mucous membrane sloughed. Besides causing great pain this necessarily converted these tracts into raw suppurating surfaces infected with many septic organisms which were inhaled into the lungs and set up a dangerous septic broncho-pneumonia. All these appearances were often seen post mortem, and I made one post-mortem on a man who had died within 12 hours in which the small bronchi and bronchioles were plugged with a muco-fibrinous clot which was pulled out like a cast of the passages.

Di-chlor-ethyl-sulphide was studied by Victor Meyer, who had published an account of it in the "eighties." It had been suggested to our War Council as a weapon in 1916, but had been refused. Now when we saw what effects it could produce G.H.Q. asked for some as soon as it could be made. We did not, however, discover the way to make it for two years, and it was not until our last advance had begun that we had it in any sufficient quantity.

We made out that its fatality was about 3 per cent. But its military effect was not to be measured by this. Its stable character and its weight caused it to cling to ground on which it had been thrown, and not only did it oblige the evacuation of a position, but it also rendered that position untenable sometimes for a fortnight. The stuff soaked through leggings and even through the upper parts of boots, so that though the box respirators preserved the air-passages and the eyes they could not protect the rest of the body from severe burns. With lesions of that character it is rather curious that the kidneys did not, as far as I know, suffer.

A certain number of cases of laryngitis with very persistent hoarseness were seen later, in which the men said that they had been in the neighbourhood of gas though without feeling any effects at the time. It seemed probable that a very slight exposure to the vapour had produced a chronic laryngitis.

The treatment of the eyes was chiefly by means of alkaline douches and castor oil drops. The throat and larynx were eased by inhalation of an antiseptic anodyne containing tr. iodi., menthol, and creosote in rectified spirit, with which a respirator was kept wet. There was no doubt of its effect, as judged by the amount of coughing in a ward where it was used. The skin was very difficult and very painful to treat. Wet alkaline dressings were usually preferred. In France, at any rate at the front, we saw only the immediate effects. Interesting sequelæ were found to occur, of which others can speak with greater authority than I.

A question which is of importance remains. Is it likely that such a weapon once employed can in future be ruled out of war? There are examples—e.g., explosive bullets against infantry—but that is, so far as I know, the only successful attempt. It is probable that any belligerent will be obliged in future to pursue researches in this direction, and to provide himself with the most dangerous gases at his command.

SOME ASPECTS OF THE TUBERCULOSIS PROBLEM.[1]

BY THOMAS D. LISTER, C.B.E., M.D. LOND.,
M.R.C.P. LOND., F.R.C.S. ENG.,
PHYSICIAN TO THE MOUNT VERNON HOSPITAL FOR CONSUMPTION.

WHEN addressing an audience on Industrial Tuberculosis at Merthyr in February, 1911, I said that "the lessons of the sanatorium must be made the basis of prevention. The real warfare must be carried on in the houses and the workshops of the people. The people must realise that it was themselves who were in the fighting line." These conclusions were largely founded on a paper that I had read at the Second Congress of the Industrial Diseases that was held in Brussels in 1910 and which was subsequently published in THE LANCET[2] of that year.

It is interesting to me to realise that there has been an evolution of ideas, and indeed a definite movement, in the direction I then indicated. Unfortunately there has been also an expansion of administrative efforts on what must be regarded as stereotyped lines. The report of the Departmental Committee on Tuberculosis, which was presided over by the then Mr. Waldorf Astor and the activities of National Insurance are familiar to most of us. Everyone realises also the great social changes that were brought about by placing an enormous army in the field and supplying its needs by munition work at home. The late Local Government Board was somewhat disturbed from its usual complacency by the discovery that tuberculosis had rapidly increased during the war. A laborious attempt at an explanation was made in a special L.G.B. report, which I really attempted to understand and have referred to in a paper on the Value and Limitations of Sanatorium Treatment published in THE LANCET of Nov. 17th, 1917 (p. 739).

In a very clearly written essay in the *Universal Medical Record* of November, 1912, two points of view were discussed, those of Robin and Calmette. Robin seems to suggest that the important thing in tuberculosis is the terrain, and that we cannot directly attack the bacillus. Calmette denies that there is a particular soil, and thinks that there is neither natural immunity from, nor predisposition to, infection by Koch's bacillus.

Sanarelli, of Bologna, wrote in 1910, at the Rome Congress on Tuberculosis, of the biological evolution of the disease, and pointed out how urbanisation was not only associated with a high incidence of tubercle, but that it was only where countries were urbanised that there had been during the last 60 years a progressive fall in the death-rate from tuberculosis.

There is no necessity for me to remind you that infection is practically universal among those who live in towns, nor for me to repeat the remark so often used in a merely sensational manner that 10 per cent. of all deaths occur from tuberculosis. We are getting tired of the constant reiteration of the fact that 60,000 deaths occur annually from consumption and other forms of tuberculosis in the United Kingdom. I will not on this occasion recapitulate the evidence as to general infection which has been so often demonstrated by post-mortem evidence and by clinical tests.

But having realised the facts to which I have briefly referred I tried to coördinate them in my own mind, and the first and chief puzzle that occurs to me is the difficulty of understanding why 90 per cent. of a population infected by tubercle do not succumb to it.

Problems of Research.

The question is whether we should try to prevent infection among the whole mass of the population or should we endeavour to prevent the occurrence of death among the small minority that succumb? If nothing less than a stamping out of consumption by the elimination of the tubercle bacilli is to content us it seems that we are setting ourselves rather a hopeless task. If, on the other hand, we desire to bring about its harmlessness there are two great problems for research which immediately suggest themselves. Firstly, why is the tubercle bacillus a comparatively harmless pest to the great majority of the population? And, secondly, why is it fatal to a minority of the population, though that minority is so enormous amongst us as to render the disease the terrible scourge it is?

This is, I think a fairly obvious and logical statement of the problem of tuberculosis, but there is no single immediate line of activity to suggest either in administration or in research which would prove the royal road to success.

If the pathologists are right in demonstrating that all men are susceptible to infection, but that only the minority are capable of fatal infection, then we have to deal with at least four factors. In regard to those who are capable of infection but do not succumb, we have to consider whether this power to overcome infection arises from something definite within themselves or something which comes from the happy external circumstances of living in which they may be placed. In regard to those who succumb when infected a similar question must arise. Is their liability to death dependent on some inherent quality in themselves or upon unhappy external circumstances?

I think we can disregard the consideration of the possibility of preventing the existence of the tubercle bacillus. It is, I conclude, impossible to disinfect the world, though astronomers promise us a complete sterilisation finally. As a practical problem we have only to consider how we should diminish the morbidity and mortality arising from the bacillus. Let us not forget that wherever civilisation has carried the tubercle bacillus and other of its advantages into populations previously not known to be affected, it has been more powerful than the weapons of war in destroying those populations. Let us remember also with Sanarelli that the fall in the death-rate has occurred in the most highly urbanised countries, which are presumably, therefore, also the most civilised. Alongside our puny efforts of national campaigns against tuberculosis which are being made in nearly every country, infinitely greater forces are at work, killing off the weaker strains of the human organism, directed by the stern rules of natural evolution. It is no doubt right from a merely human point of view for any administrative body or department that has the buzz of its machinery always in its ears, to claim that the whole of the effects which it observes are due to that machinery. My own feeling in regard to the matter of prevention is that the effect of such national campaigns, however highly organised and well meaning they may be, is at present of about as much use as the fly on the coach wheel who thinks what a dust he is making.

---

[1] Being the substance of an address before the Medical Society of Cardiff.

[2] THE LANCET, 1910, ii., 1122.

The Assistance of Natural Cure.

In the endeavour to assist Nature's cure of tuberculosis we must in all humility limit our aspirations to the endeavour to assist her methods, and at the same time try to wrest from her some of the secrets of those methods, which may be hidden in the replies to the four bald questions that I have just stated—namely, what are the physiological and environmental factors of immunity and vulnerability respectively. In other words, the first step in any government campaign against tuberculosis should be well-directed research. For nearly 40 years we have been doing homage to the bacillus by creating ingenious ambulances and all the machinery of clearing stations and hospitals while doing little or nothing to investigate the real problems of the disease. The discovery of the bacillus was such an outstanding accomplishment that we have become obsessed by it and have forgotten a good deal of the natural history of its relationship to human progress and social evolution. Nearly all our machinery has been directed to the recognition of the disease, to its appropriate therapeutics according to the individual requirements of our cases, and to the attempt to prevent infection and re-infection.

Recent correspondence in the *British Medical Journal* has supplied an object-lesson in erroneous methods. Dr. B. G. M. Baskett, in view of the close correspondence between the fall in the death-rate from tubercle and the decrease of poverty, tried to prove that the mortality was related to the real value of wages. Subsequent writers side-tracked the discussion. Dr. Baskett was right in insisting upon the relationship between the tubercle mortality and environmental factors, of which poverty may be taken as one measure. But it is not the only measure. The comparative study of industrial mortality would have shown him that there are some other points to be considered than the mere purchasing power of wages.

Local Problems.

By the courtesy of Dr. E. Walford, medical officer of health, I have been enabled to read the annual report on the city of Cardiff for 1918 and the seventh annual report of the King Edward VII. Welsh National Memorial Association. I do not know the conditions of living in the various municipal wards of the city, but I notice that the death-rate from phthisis per 1000 persons living varied in 1918 from 0·94 in Roath Ward to 5·11 in South Ward, the figure for the whole city being 1·77. This disproportionate difference between two extreme figures leads me to the conclusion that the conditions of life generally in Roath Ward are more satisfactory than those in South Ward.

I also notice that the death-rate from tubercle in 1918 for the whole city is nearly 70 per cent. greater than it was in 1910, and that in South Ward it is more than twice as great. I notice also that from 1915 to 1918 the death-rate in South Ward has trebled, while in Roath Ward it has scarcely increased. I know nothing of the wage conditions either in Roath Ward or in South Ward, but I would like these and many other points of difference between the two wards to be investigated. I would like to know what the occupations and habits are of the people in these widely differing tuberculosis areas. I should like the physical standards measured. I would like to know whether wages have increased in the South Ward during these last years, and whether the people themselves show any understanding of how their increase in wages, if any, should be spent to hygienic advantage. Has there been an invasion of unhealthy people? Has tuberculosis been better recognised in the South Ward?

The statistics of the report also show that the death-rate from phthisis is 50 per cent. greater even in 1918 than the average rate for ten years from 1908 to 1917, but it was increasing throughout the duration of the war. This is a common experience of the whole country, and Cardiff, although one has good reason to believe that it has not been lacking in prosperity during these past five years, shows even a greater increase in its tuberculosis mortality than the average of the country. But as I have pointed out, the increased mortality is disproportionately borne by certain wards of the city. I would like to know why. In other words, these figures, like all the figures relating to tuberculosis, show that there is an intimate association between a heavy phthisis mortality and some social conditions. This is a question of policy and not of politics.

Measures for Prevention and Treatment are not Identical.

Fresh suggestions are continually made for increasing the expenditure of public money on treatment. When sanatorium methods apparently fail to secure any permanent benefit for cases of industrial tuberculosis, we suggest increased segregation of the advanced cases, farm colonies for the chronic cases, after-care committees, and especially more officials, both lay and medical. No wonder the medical officer of health of Edinburgh, the place of origin of the tuberculosis dispensary system, complained early in 1917 that our methods are upside down. For years past I have been pointing this out so far as tuberculosis is concerned.

When a patient has been discharged from a sanatorium with his disease arrested we know that something called resistance has prevented the further extension of his illness, and that he has obtained this something under sanatorium conditions. We know also, however, that before he went into the sanatorium he must have been under different conditions where his resistance was broken down. We send our successes back to these same adverse conditions, and the public complains that the sanatorium is no good because they relapse.

It is very interesting to me, who have for over ten years recognised this anomaly, to see that the idea has gradually dawned on our publicists that we might as well try to provide such conditions of life and labour as would render the expensive sanatorium unnecessary. Not only would such conditions prevent a large amount of tuberculosis, but also many of the other evils associated with bad surroundings. The medical practitioner has always been in advance of the hygienist in this matter. Whenever I have discussed the problem of tuberculosis with individual practitioners they have always said to me that it is a disease depending on social conditions, which on the one hand destroy resistance, and on the other favour infection.

It is to the social conditions that research should in the first place be directed. We must no longer be misled by such shibboleths as a phrase in a Local Government Board Report which states that measures for treatment and prevention are largely identical. We must, on the other hand, insist that prevention is an entirely different problem from treatment, and requires an entirely different machine. We cannot "treat" until we have failed to "prevent."

Some small attempts have already been made in this direction during the war, and a report published in 1915 by the Medical Research Committee on "The Incidence of Phthisis in the Boot and Shoe Industry" was a move in the right direction. I went much further in a lecture given at the Institute of Hygiene in April, 1914, on "Consumption and its Prevention." I claimed then, and I still say, that systematic research on uniform lines, not only in regard to occupation but in regard to all the functions of communal life in any group of the population showing a high tuberculosis mortality, is the proper method of approach to the problem. It must not be supposed that, though I recognise the need for sociological research, I ignore the necessity for the fullest pathological investigation of the clinical problems of tuberculosis. Let us turn for a moment to the last report of the Welsh National Memorial Association. It deals almost entirely with questions and statistics of treatment, though I am glad to say that it reiterates its objects as including the prevention and eradication of tuberculosis in Wales, and, in particular, the provision of treatment. The special report appended on the medical policy of the association is, however, of interest. The governors of the association decided in July, 1917, to ask the Council to consider the steps which should be taken to develop the preventive side of the work. The special report is in two sections, eleven pages still dealing with treatment and only seven with prevention. It is probably familiar to those practising in Wales, and I need not therefore recapitulate it. Briefly, the section dealing with treatment points out that medical practitioners, including school medical officers and others, are invited to refer to the tuberculosis officer cases, both diagnosed and suspected. Clinical diagnosis is said to be the most important duty of the tuberculosis officer. Treatment is considered under various headings and many groups of patients are defined. The aid given by the subordinate officers, such as health visitors and district nurses, is also indicated, and a considerable space is allotted to institutional methods.

Coöperation of the General Practitioner.

But I do not see in Wales, any more than in England, that there is much direct encouragement and support to the practitioner. I should surmise that much more use could be made of practitioners in Wales as in England if their time and services were adequately remunerated. I consider that the general practitioner should be the backbone of all measures undertaken for the diagnosis and treatment of tuberculosis, as he should be of all clinical work, and it is a mistaken policy which limits the public recognition of the power to make an early diagnosis to too few individuals. The interest of the practitioner in tuberculosis is liable to be restricted to the comparatively advanced cases, and distrust of their medical attendants is encouraged amongst the public. What seems to me desirable in every public institution where the tuberculosis officer is in attendance, whether dispensary or otherwise, is that the local practitioner should be asked to coöperate as a co-director and be adequately paid for his time and services. The private surgery and the absence of trained helpers render it difficult for the practitioner to give the same services as he could professionally well give when working as an associate of the tuberculosis officer so far as clinical work is concerned. Provided that proper remuneration were offered, there seems little reason to fear that there would not be sufficient doctors to make an adequate rota in the week's work. The advantage to the public would be the keener interest that men would acquire in the early recognition of the various manifestations of tuberculosis. The tuberculosis officer would be rapidly relieved of a great deal of what is the simplest kind of repetition work. In England, perhaps this does not apply to Wales, the tuberculosis officer has little time for anything but clinical work. Apart from the examination of sputa for the bacillus, he is unable to direct the channels of pathological investigation or to scrutinise minutely the population under his care. Under some system of coöperation as I have suggested the skill necessary for the recognition and classification of the various groups of cases would be rapidly acquired by the practitioner. The tuberculosis officer would be enabled to devote some of his time, which is at present largely wasted, to the important problems of prevention. I know the amount of training that many tuberculosis officers have received before they were appointed. There is no doubt in my mind that equal clinical skill is easily within the reach of most general practitioners who are desirous of acquiring it. Moreover, all general practitioners have that experience of general diseases which is frequently lacking in the young "expert."

The Interpretation of Technical Terms.

When I turn to that section of the special report which deals with the problem of prevention I am struck with the completeness with which the problem is identified as being merely one of infection by the bacillus. Even the section on research suggests very little except work on the virulence and infectivity of the bacillus. There are other problems for the pathologist who would escape from routine methods, such as the antithetic relationship of gout and tuberculosis, if it exists, and the problem of the endocrine secretions and the modern revival of the doctrines of "diathesis" and "constitution." What do these things really mean?

We are a profession that loves to disguise its appalling ignorance. Lawyers, who seem to be our natural enemies, often taunt us with our smug substitution of a polysyllabic word of doubtful etymology for what might be expressed in simple English. Many a patient is comforted by being told that they are suffering from pleurodynia when they complain of a pain in the chest. We speak of a strong or a weak "constitution" and only occasionally wonder what we mean by it. The short-sightedness with which Parliament framed the Insurance Act has tended to perpetuate symptomatic treatment and the bottle of medicine. I believe Sir Clifford Allbutt has pointed this out on many occasions.

I would like to refer very briefly to some of the suggestions in Sir George Newman's Outline of Preventive Medicine as to the question under discussion. He says on p. 74, when dealing with this subject, "frankly many authorities directly responsible for dealing with this disease are at present merely playing with it," and sums up this particular section by saying—

> "It is obvious that much remains to be done. The standard of diagnosis in tuberculosis, the scope and duties of the tuberculosis officer and tuberculosis nurse, the managemant of residential institutions, the education of the patient and his after-care, the relation of the disease to industry and tuberculous milk, the investigation of local high incidence, the subject of non-pulmonary and surgical tuberculosis—all these questions call for careful attention and some of them for immediate action."

On pp. 96 to 98 a series of questions are postulated for diseases in general, which it would take the whole army of medical men in this country the whole of their time to investigate supposing even that they were adequately trained and equipped. I do not say that it is probable, but it is perhaps possible that greater good could be derived by so employing the whole of the profession than by treating the symptoms of disease by pills and potions. It is certainly impracticable, and though the lasting good to posterity would be incalculable, yet those of us who have the misfortune to be mere clinicians realise that the present generation would suffer even more than they do at present from the drug vendor.

If, however, such questions were answered even for only one great group of diseases—namely, those we recognise as tuberculosis—a great many of the other questions relating to allied affections depending on lack of hygiene would also be solved. The questions are based on the evolution in ideas which has occurred during the last ten years.

It is always dangerous ground to tread upon when one arrives at conclusions that the methods in vogue are not the last word in practice. Those who are cogs in the administrative wheels cannot conceive that they should ever be in any different relation to their work than the relation in which they stand to the neighbouring wheel. Having set up an engine, we are particularly liable to continue its use even when its inefficiency has been demonstrated.

I would like to say here that I do not for a moment claim that my own views have been any more than an early part of the general evolution that is taking place in regard to tuberculosis. But Sir George Newman shows throughout the greater part of this Memorandum such a large grasp and imagination that we may almost wonder at its being the outcome of an official mind.

I would like to quote one remark on p. 101 of the report, dealing with an adequate medical service. He says that the "foundation of the medical service is the medical practitioner, he is its pivot, its anchor, and its instrument."

The Improvement of Conditions for the General Practitioner.

But he goes on to talk about the necessity of improving the facilities of the practitioner for post-graduate instruction, for improving facilities for practising his profession, and even suggests that—

> "He should be provided with the means to help himself in his struggle against desperate, indeed almost hopeless, conditions—without assistance, guidance, or coöperation which is readily available, without laboratory facilities, without nurses, without ample clinical and hospital accommodation. All the State appears to have done is to take away his patients—tuberculous, school children, venereal disease—instead of strengthening his position, equipment, and capacity to deal with them himself."

In concluding his remarks on the general practitioner he quotes Sir Bertrand Dawson's statement that—

> "The general practitioner's outlook needs to be more comprehensive. In him should be realised the correlation of preventive and curative medicine. He should concern himself with the Ministry of Health as well as disease; he must be brought into the condition of a rightful leader and skilled adviser in all that appertains to the social service and welfare of his district. In matters of health he should be the father of his people."

I think we all know where the difficulties lie in one respect. I think the medical practitioner is rather tired of getting good advice. If I am right in my surmise as to the different conditions that prevail in the South Ward of Cardiff from those which prevail in other wards with a much smaller tuberculosis mortality, the practitioner in South Ward would be glad to see some of these facilities. I am not quite sure what is meant by facilities, but I do not see how it is possible under existing conditions of general practice for the practitioners to make use of these facilities, post-graduate study, clinics, tuberculosis officers, and all the rest of it unless he is made a willing, and that means adequately paid, member of the medical service. The remedy should lie in his own hands, but the very conditions under which he works seem too often to have destroyed his initiative, and rendered him an object of criticism for those who say falsely that his only natural desire is his personal benefit.

Nevertheless at a recent conference of Panel Committees in England the representatives of the panel doctors themselves turned down the discussion of "practitioners' clinics." Under the present conditions of general practice they saw no use in considering the question. In other words, although they claim justly that there should be an increase in their capitation fee, the competitive needs of themselves and families prevailed against the possible benefit that could be derived from combined practice, and they have created the impression that they do not desire to give a better service.

Conclusion.

Some of you may remember a letter which THE LANCET and the *Times* published at length, written just before the Insurance Act came into force, at the end of negotiations which then took place between the profession and the Government. I then suggested a similar coördination in clinics, which has now been re-discovered as "team-work." This now has the approval of not only leading practitioners but also the chief medical officer of the Ministry of Health.

But neither Sir Bertrand Dawson nor Sir George Newman can expect general practitioners to regard this necessity as one they are willing to coöperate in providing until some guarantee is given. The medical practitioner requires a little more invitation and a little less telling. He wants less depreciation and more appreciation. His part in solving the problem of tuberculosis should be that of diagnosis and treatment. He should be the willing co-director of all the agencies established to enable him to carry out these functions. Medical research should involve much more than staining sputum, and there is enough work in tuberculosis alone, if all its aspects are to be studied, to keep the Medical Research Committee quiet and busy for some time to come. But if they were considered a great many other questions would cease to require solution.

These two points I would like specially to emphasise. Tubercle is the index disease of social conditions, and the severest test of our clinical skill, and can only be approached successfully when we begin to understand something of the causes of health among the infected. It is not merely by the diagnosis and treatment of those who are unhealthy among the infected that we shall ever solve this problem.

ABSCESS OF THE LIVER

AMONG BRITISH EASTERN TROOPS.[1]

By A. L. CANDLER, F.R.C.S. Eng., M.B., B.S. Lond.,
ASSISTANT SURGEON, ROYAL DEVON AND EXETER HOSPITAL.

THERE are several severe tropical diseases to which those who have been on service in the East are subject after return to this country. As surgical specialist to British general hospitals in Salonica, Mesopotamia, and the Punjab I have had an opportunity of learning about, and dealing with, inflammation and abscess of the liver due to infection by *Entamœba histolytica*, and therefore venture to deal with this disease in the hope that my experience may be useful to others who have not hitherto had the opportunity of meeting such disease, but who may do so among demobilised troops.

Inflammation or abscess of the liver occurs not infrequently after the bowel has been infected by the *Entamœba histolytica*, and is therefore a late complication of amœbic dysentery, but it is certain that patients suffer from amœbic inflammation and abscess of the liver who have not had diarrhœa or any symptoms which made them suspect that their bowels were infected by the amœba. In 3 cases of hepatitis and 13 of tropical abscess of the liver under my care only 3 had knowledge of having had diarrhœa or dysentery; the patients were British and could be credited with intelligence. Osler mentions that in 27 cases 5 had no dysentery, 2 had normal mucosa, and 2 had *old* scars in the large bowel. Rogers mentions 18 per cent. of cases without history of dysentery. In 1 fatal case under my care there was no lesion of the bowel except one small healing insignificant ulcer in the ascending colon. In my other fatal case the bowel appeared normal post mortem. In the fæces from 12 of my cases amœbæ were found by the pathologist in 3 only. It therefore appears that patients who have had an amœbic infection so slight that it did not cause diarrhœa or dysentery, and was therefore not treated, are more prone to infection of the liver than those whose infection caused diarrhœa, dysentery, diagnosis, and treatment. This point is obviously important in considering the history for diagnosis.

In amœbic dysentery the large bowel is ulcerated, with undermining of the mucous membrane, and it is in the walls of the ulcer that the amœbæ are found most plentifully. It is stated (Osler) that amœbæ have been found in the portal capillaries, and this channel may be their route to the liver. On arrival they may cause either a general hepatitis or one or more abscesses. Such an abscess has an inner necrotic wall surrounded by an area with increased connective-tissue cells squashing the liver cells, while outside this is an area of hyperæmia. It is remarkable that there is no great local leucocytosis unless the abscess is secondarily infected with pyogenic organisms.

The pus is usually greenish-yellow and slimy, and not often pinkish according to the objectionable description "anchovy sauce"; the pus is sterile to ordinary organisms, this point clearly differentiating the abscess from one caused by the more ordinary Western infections. It is difficult to find the amœbæ in this pus, but they are more easily found in the drainage-tube later, the explanation being that the tube touches the abscess wall in which the amœbæ are more plentiful and that they pass direct to the tube.

The abscess usually starts deep and nearly always in the right lobe. I have had no experience of multiple small abscesses; it is far commoner for the abscess to be solitary. It enlarges, and in so doing destroys liver substance and encroaches either (1) towards the ribs; or (2) beneath the diaphragm, through which it may perforate into the lung or pleural cavity; or (3) towards the epigastrium, bursting through the abdominal wall into the peritoneal cavity or a hollow viscus. I have seen a small Arab girl in whom a hepatic abscess had burst through her right rectus abdominis. Osler mentions nine rupturing into lung, three into pleura, and three into vena cava. In encroaching towards ribs or diaphragm it causes local dry peritonitis or pleurisy and therefore pain, diminution in movement of the diaphragm, and congestion of the base of the lung; it is important to note this sequence of events, for they are liable to lead to false diagnosis in cases seen late in the disease; in pushing the diaphragm upwards and outwards it diminishes the costo-diaphragmatic space, thereby making the surgical approach to the cavity much easier, and lessening risk to the patient's pleural cavity.

Diagnosis.

Diagnosis is difficult. Sir Leonard Rogers states that in 30 European cases 50 per cent. had had fever over one month before the abscess was found, and 34 per cent. between two and four weeks. The onset is insidious. There may be a history of diarrhœa or dysentery, but in my experience, as already stated, there is no such history in the majority of cases; in fact, there is often one of constipation. Similarly, amœbæ are often not found in the fæces. The general condition of the patient varies with the size and chronicity of the abscess; patients who have been ill two or three weeks are slightly sallow without jaundice, thin in the face and drawn in expression, with some anæmia; content to lie still but having pain on movement of the trunk, situated usually over the right lobe of the liver. In the early stages there is no pain at all. If there is perihepatitis or pleurisy pain is present when a deep breath is taken.

The pulse-rate is about 100 to 110, or even lower, the fever being continuous but not very high—101° to 102° F. But both pulse-rate and temperature may be lower than the figures given, and yet a considerable amount of pus present with destruction of liver substance. The temperature of one patient is of interest, as he had first a right epigastric abscess and later one high up in the right lobe; the latter contained about 10 ounces of pus, and yet previous to the second operation he was apparently improving according to his chart alone; the chart gave a false impression—he was emaciated, anæmic, and very ill, with half a pint of pus in his liver, yet during the ten days previous to operation his pulse-rate rarely reached 100, and his temperature was not above 101°.

---

[1] A paper read before the Devon and Exeter Medico-Chirurgical Society on Dec. 18th, 1919.

An abscess coming downwards to the epigastrium is fairly easy to diagnose, as the local tender enlargement can be felt and easily approached. Difficulty occurs when the abscess is in its more common situation beneath the ribs and diaphragm. There is often some slight œdema or bulging of the chest wall over the abscess; the liver may be felt slightly enlarged beneath the costal margin, and its upper level of dullness may be raised; one very characteristic feature is a dome-like rise in the area of the liver dullness below the axilla. I suggest that this is due to the fact that the diaphragmatic muscle is longer at the side than in front or behind as it passes from thoracic wall to three-lobed central tendon and that the muscle is stretched more easily than the central tendon, allowing liver to expand in the side to the costal wall, but not in front or behind. Tenderness on pressure over the region of the abscess is present, and its maximum point is a guide to the position of the abscess.

Limitation in movement and upward bulging of the diaphragm can be seen by X ray, and such examination is a great help in diagnosis, but I have not seen an abscess *in* the liver photographed. If an abscess be low down in the liver the diaphragm is not limited in movement, and I feel sure that one of the serious complications and also difficulties in diagnosis is that limitation of movements of the diaphragm and lower ribs, due to inflamed pleura, peritoneum, and liver, causes congestion of the base of the right lung, which easily becomes infected with pyogenic organisms. This means increase of fever, pulse-rate, and leucocytosis, while the inflamed lung is liable to disguise inflamed liver below and beneath it. This seems so important that a summary of such a case is worth putting forward.

A man obviously suffering from some severe disease was in one of my wards for five weeks, and was seen by the consulting surgeon and physician to the Forces and by other medical officers; he died with a large abscess in each lobe of his liver. I had explored his liver by multiple punctures on two occasions under general anæsthetic. He had severe inflammation of the base of the right lung and later of the left lung, coughed up streptococci and pneumococci, and had a leucocytosis of 21,000 with polymorphonuclear increase. As puncture failed to find pus in his liver he was considered to be suffering only from infection of lungs. Post mortem his liver was a shell containing two large abscesses without any enlargement of liver downwards or upwards, but with marked inflamed adhesions to diaphragm and peritoneum and severe inflammation of bases of lungs and bronchi.

I feel that this man should have been diagnosed, but the "red herring" of inflammation of the lung and failure to find pus by exploring punctures put me off the track.

Leucocytosis is uncertain in an uncomplicated tropical abscess of liver; it can be as low as 4700 and as high as 28,000; in my opinion the high leucocytosis is often due to inflammation of the base of the lung rather than to the abscess in the liver. It is also a remarkable fact that the wall of the abscess cavity is not crowded with leucocytes as in an infection by pyogenic organisms. The percentage of polymorphs is not increased, being 70 to 80 per cent., while lymphocytes are about 8 to 15 per cent.; the differential leucocyte count thus gives a further point distinguishing abscess due to amœbic infection from that due to pyogenic organisms, but this difference will not hold good i the lung is inflamed.

The ultimate diagnosis is the finding of pus, an this is searched for by puncture, preferably with long trocar and cannula, like Barker's lumba puncture needle, and under general anæsthesia Multiple punctures are often necessary, the needl being withdrawn to the skin before change o direction, otherwise the liver will be torn; a goo well-fitting syringe is necessary, and even wit these precautions it happens not infrequently tha pus is missed. I suggest that one reason is tha the liver will not collapse easily, and therefor suction is made against a vacuum; also the pus i mucoid and thick, and the explorer perhaps ha qualms about large veins in the liver. There ar remarkable cases of hepatitis where puncture have been made in search of pus in inflamed liver followed by rapid cure of liver and patient; on man with hepatitis recovered within 24 hour after puncture, his liver going back to normal size tenderness disappearing, and fever stopping.

But if it is strongly suspected that there is a abscess and puncture fails to find pus, in m opinion an epigastric incision should be made an the liver surface felt by the hand passed under th diaphragm. By this method I found an abscess i the liver near the middle line under the righ costal cartilages; it did not contain more tha 3 drachms of pus, and I had failed to find it b puncture, as one would expect in such a case. O another occasion I felt fine recent adhesion between the top of the liver and diaphragm I closed the epigastric incision and resected the ri just above the adhesions, draining an abscess containing 3 ounces of pus which I had failed to find by puncture. One is dealing with a severe disease difficult to diagnose, difficult to locate, and causing destruction of liver, and it is all-important to dea with it early. I therefore feel that an exploratory epigastric incision should be made early if emetine and puncture fail in a case where the disease is suspected.

Treatment.

The treatment of hepatitis due to amœbic infection is hypodermic injections of emetine, which rapidly cause the disappearance of pain, enlargement of liver, and fever. If they persist it is probable that an abscess is present. In Mesopotamia and India emetine hydrochloride was given hypodermically in 1-gr. doses daily, sometimes twice daily for the first few days. I heard that some hearts were damaged by too much emetine, but I saw none. It is said to be cumulative in effect and so the injections are discontinued after ten days and a further course of injections given later if necessary. Bismuth emetine iodide was given in pills for dysentery, but in my experience they caused nausea and vomiting, which did not happen with hypodermic injections of emetine hydrochloride: it is interesting to note that the pills were reported for a period not to cause nausea and vomiting until some enthusiast discovered the pills unchanged in their coats in the fæces.

If an abscess is present it must be drained either by epigastric or by costo-diaphragmatic route. Epigastric draining is usually easy and, provided that the peritoneal cavity is packed off before the abscess is opened, there is little risk of infecting the general peritoneal cavity. Cathcart's method of putting in the drainage-tube on the stretch is useful, as in expanding it closely fits the hole of entry into the liver. It is almost unnecessary to ay that as little damage as possible to liver and ts vessels is caused, blunt instruments being used. f drainage is made through the thoracic wall, ½ inches of rib are excised, as in operating or empyema; but before the posterior periosteum at the site of the excised rib is opened, deep catgut sutures are passed by a fully curved small needle, suturing diaphragmatic muscle to intercostal muscle above and below the area of rib excised; by this means the pleural cavity is shut off, and risk of pneumothorax or empyema is diminished; the diaphragm is usually so pushed towards the thoracic wall that the costo-diaphragmatic space is diminished, and it is easy to suture diaphragm to intercostal muscles, and also to incise the periosteum and the diaphragm without going through pleura in many cases. Two medium-sized tubes are better than one large one, as they allow of irrigation later without pressure.

Aspiration of the abscess has been advocated; when the abscess is found by puncture it is aspirated as far as possible, and then a solution of 20 gr. of quinine sulphate in 2 ounces of water are injected before the needle is withdrawn; I am told that if this is done it is probable that the abscess will be cured, but that it is uncertain and recurrence is more likely than after drainage.

After-treatment consists in the hypodermic injection of emetine and careful sterility in dressing; the pus is sterile to pyogenic organisms, and if the cavity becomes infected by them there will be prolonged discharge and sinus at any rate. I believe that the tubes should be removed as early as possible—that is, as soon as the slimy purulent discharge has ceased—usually within a fortnight to three weeks; it is the emetine which will ultimately kill the amœba, not the drainage, and if the tube is left in long the chances of secondary infection and persistent sinus are increased. I have seen liver abscesses drained by epigastric and by costal route heal within six weeks, but the tubes were removed early; others of my cases had to be evacuated and I do not know how long they took to heal, but in all cases the tubes had been removed and the patients observed for a few days before evacuation.

The pathologist, Captain C. C. Twort, examined the behaviour of active amœbæ in eusol and it is interesting to know that the amœbæ crawled and were active at first in ordinary eusol. After five minutes they were rounded and motility was slow; after half an hour they were still motile but feebly so. Therefore eusol does not kill the amœba, but only diminishes his desire to crawl. Motile bacteria quickly became immotile in the same eusol; it is advisable in after-treatment therefore to irrigate the cavity with a solution of quinine sulphate, 10 gr. to the ounce, after washing away the pus with saline or peroxide. In the after-treatment of a liver abscess the fæces should be examined for amœbæ, if these have been present earlier, as the patient is not cured of the disease if amœbæ are present in the fæces and a further course of emetine will be necessary.

Differential diagnosis mainly concerns malaria and the hepatitis accompanying gall-stones and typhoid. In malaria the finding of the parasite, enlargement of the spleen, and improvement with intramuscular injections of quinine bihydrochloride usually make matters clear, but in the East the patient may have both diseases.

In its early stage, before localising signs occur, an abscess of the liver may resemble typhoid, particularly when the leucocyte count is as low as 4700, as in one case; in more than one instance patients were observed for a week as doubtful typhoid before local signs of trouble in the liver occurred.

Prognosis depends on the time of diagnosis, treatment, and the amount of liver destroyed. It is astonishing how much liver can be destroyed and yet the patient recover; one patient had an abscess in his right lobe containing two pints of pus; another had at least one-third of his total liver substance destroyed by a gunshot wound and resulting suppuration; there was only a very slight liver shadow by X ray at the outer right third of his liver; he had an abscess from Poupart's ligament to scapula; he was emaciated and dangerously ill, but ultimately recovered sufficiently to be evacuated from Salonica to England, having put on a considerable amount of weight. In considering the prognosis, it must be remembered that a second abscess not uncommonly occurs months later, but I guess that this is less frequent since the introduction of efficient treatment with emetine.

Death-rate in this disease used to be very high; with the growth of pathology and surgery and the use of emetine the prognosis is greatly improved; in my small experience of 13 cases of abscess of the liver 5 were drained through the epigastrium and recovered, 7 were drained through the chest wall and diaphrágm of which one died. He was very wasted and worn out on admission, and was unable to granulate and repair his abscess cavity; he lived 15 days after operation, and post mortem revealed no trouble other than the cavity of his abscess, efficiently drained, but with its walls necrotic, showing no signs of repair; one case was undiagnosed and died.

Three cases of hepatitis recovered who were all diagnosed clinically as amœbic.

Conclusion.

In conclusion, points of importance are:—

1. Often there is no history of diarrhœa or dysentery.
2. Often no amœbæ are found in the fæces, and even in fatal cases little or no ulceration of the bowel is found post mortem.
3. Fairly low temperature, pulse-rate, and leucocytosis are not always contra-indicative of the presence and quantity of pus.
4. The liver may not be enlarged downwards, or only slightly so, because of necrosis around the abscess occurring rather than the liver enlarging or being pushed downwards.
5. If the puncture fails to find pus in a case diagnosed clinically, an epigastric incision should be made in an attempt to get a scientific early diagnosis and treatment.
6. Drainage should be free, followed by daily sterile dressing and a course of emetine hypodermically.
7. The drainage-tubes should be removed as early as possible to prevent secondary infection and sinus formation.
8. Inflamed lung is liable to disguise inflamed liver below and beneath it.

LITERARY INTELLIGENCE.—Messrs. G. Bell and Sons announce for publication within the next fortnight Dr. Edridge-Green's new book on "The Physiology of Vision, with Special Reference to Colour-Blindness" (price 12*s*. net), and also the same author's "Card Test for Colour-Blindness" (price 25*s*. net).

INFLUENZAL PNEUMONIA:

THE INTRAVENOUS INJECTION OF HYDROGEN PEROXIDE.

BY T. H. OLIVER, M.A., B.CH. CANTAB., M.D. VICT.,
RESIDENT MEDICAL OFFICER, THE ROYAL INFIRMARY, MANCHESTER;
AND
D. V. MURPHY, M.B., CH.B. N.U.I.,
CAPTAIN, R.A.M.C.

IN view of the possibility of a further outbreak of influenza accompanied by broncho-pneumonia, another method of combating the extreme toxæmia and anoxæmia appears to be worthy of record, more particularly so as the clinical importance of the latter has recently been discussed by Professor J. S. Haldane.[1] It is noteworthy that in his paper he lays especial emphasis on the primary need of oxygen *in solution* in the blood.

Theory Underlying the Treatment.

There occurred in Busrah in June and July, 1919, a severe epidemic of influenza, most marked among Indian troops, and accompanied in many cases by an exceedingly toxæmic and fatal broncho-pneumonia. It is unfortunately impossible to give statistics of the mortality of the epidemic, but its extent may be gauged from the fact that in one large Indian hospital in which the influenza cases were segregated in special huts the death-rate was over 80 per cent. in the pneumonia cases with toxic symptoms.

So useless were the usual remedies tried in this latter class of case that we felt justified in giving a trial to any method which held out a prospect of success. It had been observed by one of us (T. H. O.) some years previously that an ammoniacal solution of hydrogen peroxide had, in the presence of a catalyst (copper), a remarkable oxidising power on morphia.[2] Further investigation, as yet unpublished, showed that many other substances were similarly oxidised by this solution, the power of which appeared to depend primarily on the formation of nascent oxygen.

We thought that use might be made of this reaction if the H_2O_2 were given intravenously, in this instance employing the well-known catalytic powers of hæmoglobin as a substitute for the copper, and we hoped thereby, not only to supply oxygen to the tissues with greater rapidity than by the ordinary methods, but also to render the circulating toxins inert by oxidation. The obvious danger was gas-embolism, against which most text-books warn those using H_2O_2 even to wash out serous cavities. We believed, however, in the first place, that pure oxygen, if given sufficiently slowly, would be absorbed before any embolic symptoms developed, and secondly, that the air-embolism known to surgery is really a misnomer for nitrogen embolism.

Effect on Patients.

The first case was an Indian with broncho-pneumonia of influenzal origin and intensely toxæmic. He had been delirious for two days previously, and was selected as being the worst case in the ward and to all appearances moribund. Two ounces of a ten-volume solution of H_2O_2 were diluted with 8 ounces of normal saline, and the solution made slightly alkaline with 5 minims of liquor ammoniæ. This produced a faintly effervescing solution. The median cephalic vein was exposed by open dissection, and the solution infused through a glass cannula attached to a Rogers cholera apparatus.

The solution was infused very slowly, a complete stop being made for half a minute in every four. Small bubbles were allowed to enter the vein unchecked, but if a large accumulation of oxygen appeared in the cannula the transfusion was checked for about a minute until it had gradually entered the vein. The whole transfusion lasted for 15 minutes. The patient showed no signs of discomfort until towards the end of the operation, when he became slightly restless. This, however, passed off in a few minutes, and there were no other untoward symptoms except a moderate rigor which occurred two hours later. After the rigor the temperature, which had been 101·8°, fell to normal and remained so for 36 hours, when it again rose to 101°. The latter rise was not accompanied by toxic symptoms and the temperature gradually fell to normal in the course of the next ten days. The change in the mental condition was remarkable, the patient, who previously had had to be tied in bed owing to delirium, was within six hours of the injection sitting up and asking for food; he slept well the next night and from that time improved in every way, eventually being invalided to India as a walking case three weeks later.

Encouraged by the apparent success in this case, we tried the method on 24 others—cases of influenzal pneumonia—selecting always those whose condition was apparently hopeless. Of the total of 25 cases, 13 recovered and 12 died, a mortality of 48 per cent. Of the 12 who died, 9 showed no visible effect for either good or ill. In 3 there was a temporary improvement. One case only died within five hours of the infusion, during a rigor. One of the cases had four injections at intervals of three to five days without any sign of gas embolism, nor did we find any signs of such embolism post mortem. Of the 13 who recovered, 10 were delirious at the time of infusion and had to be held down in bed. Three were comatose from toxæmia.

The average respiration-rate before the operation was 46 per minute, the greatest being 60 and the least 28. Within 24 hours of the infusion the average rate was 31·5, the greatest fall being from 60 to 24. The noticeable feature, however, was a steadying and deepening of the respiration and a great lessening of the discomfort. The average pulse-rate before infusion was 118. 24 hours later the average was 98.

The temperature in this epidemic was, apart from complications such as malaria or effect of heat, rarely high and usually 101°–103°. In all cases but one the injection was followed by a rigor, after which (except in two of the cases) the temperature fell to normal. Of the two exceptions one remained with the same temperature as before, the other fell from 102° to 100°. The afebrile period lasted usually for 18–36 hours, after which the temperature again rose to 99°–101°, and fell by lysis in 4–7 days.

At this juncture we would point out that the occurrence of a rigor or a fall by crisis is exceeding rare in Mesopotamia in cases of pneumonia. Neither of us remember such an occurrence in an experience of 3½ years among British and Indian troops. As regards the toxæmia, we believe that the frequent occurrence of a rigor and a complete or partial crisis, combined with a rapid improvement in the patient's general and mental condition, indicated that this was overcome in many instances. Whether this was by merely supplying oxygen to devitalised tissues, or whether direct oxidation of the circulating toxins took place, it is not easy to say. It is difficult to believe, however, that so small a quantity of oxygen as is contained in

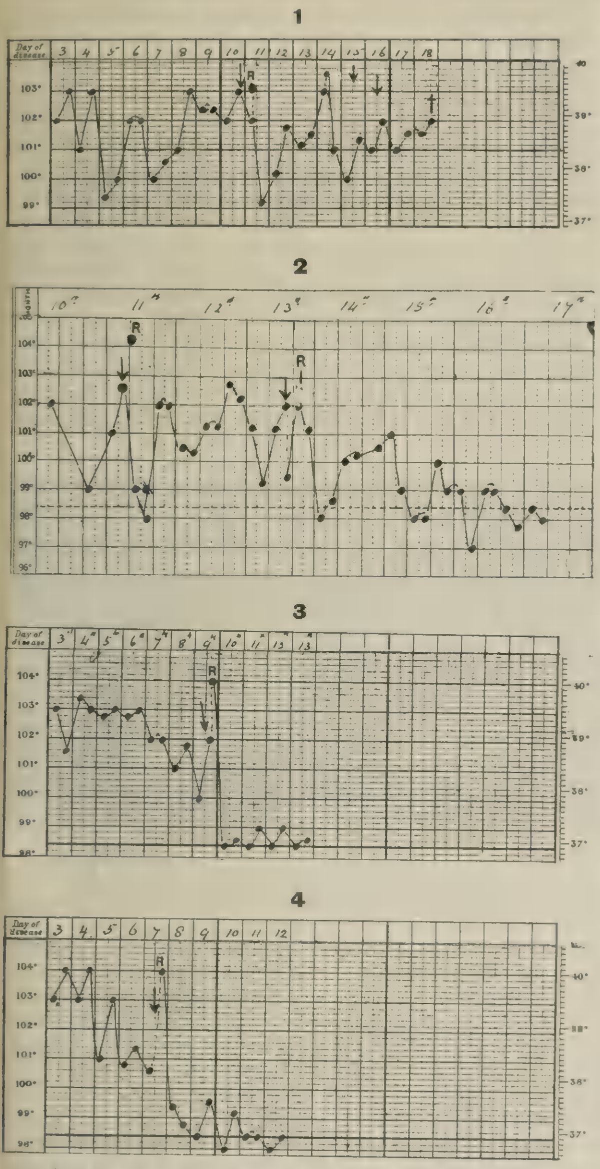
Charts of Four Cases in which Hydrogen Peroxide was given Intravenously.



An arrow denotes an injection. R = rigor. The first case ended fatally, the others recovered.

2 oz. of H_2O_2 could produce these effects other than by its nascent oxygen, and this view is supported by a trial we made in a case of toxæmia arising from suppurating inguinal glands in which there was no question of anoxæmia. Here the general improvement which so rapidly took place could only be ascribed to direct oxidation.

The accompanying four charts will give some idea of the reactions obtained in one fatal and three recoveries; in the first it will be seen that four injections were given, the first two of which produced a rigor and temporary improvement. In the second two injections were given, each producing a rigor and some improvement both in pulse and respiration rate. In the third and fourth the injection was followed almost immediately by a rigor and subsequently by a crisis. In all these cases there was marked slowing of the respiration-rate after the injection.

Technique.

A strength of 2 oz. H_2O_2 in 8 oz. of normal saline was usually used. In one case 3 oz. H_2O_2 was used without any ill-effect. Fifteen minutes was allowed for transfusion and this was checked temporarily every four minutes, or whenever large bubbles of oxygen appeared in the cannula, or if the patient became at all restless. Small bubbles entering the vein did not appear to do any harm. In one case the patient struggled so violently in his delirium that the cannula slipped out and the distal ligature came off. On pressing the vein above two distinct streams could be seen to issue from the wound, the one above bright red and frothing, the other deep blue.

The epidemic ceased almost as suddenly as it had begun, so we were unable to try the method on earlier cases or to give a more extensive trial to repeated injections.

Conclusions.

From our experience we conclude that—

1. H_2O_2 can be given intravenously without gas embolism being produced.
2. The anoxæmia is often markedly benefited.
3. The toxæmia appears to be overcome in many cases.
4. The mortality (48 per cent.) compares very favourably with the 80 per cent. in similar cases not so treated, and more so when it is remembered that we only treated the most severe and apparently hopeless.

ANÆSTHESIA IN THROAT AND NOSE OPERATIONS.[1]

BY FELIX ROOD, M.B., B.S. DURH.,
ANÆSTHETIST, UNIVERSITY COLLEGE HOSPITAL.

[THE author pointed out that operations upon the ear, nose, and throat are not generally serious in themselves, and that it is, therefore, of primary importance that the technique employed should be as free from risk as possible. After dwelling on the risks of chloroform and mixtures containing it and the comparative safety of ether, Mr. Rood advanced the following arguments in support of his contention that "ether is the proper anæsthetic for operations upon the nose and throat."]

The Degrees of Anæsthesia.

It will be necessary to speak of two degrees of anæsthesia—deep and light. I should like to define what I mean by this. In deep anæsthesia the respiration is regular, automatic, and shallow, the larynx and pharynx are absolutely paralysed and immobile, and respond in no way to stimuli; the recurrent laryngeal nerve is paralysed and the cords stand in wide abduction. The pupil is generally dilated and does not react to light. All reflex activity of the pharynx and larynx is abolished, a Brünings tube can be passed into the larynx, and there is no interference with the quiet rhythm of respiration and no spasm of the cords. The patient in this condition can take no active part in his own operation, he cannot cough. On the other hand, he cannot obstruct his own respiration by laryngeal spasm. If this degree of anæsthesia is induced with ether the patient is pink and rosy, with a full regular pulse of about 80–91.

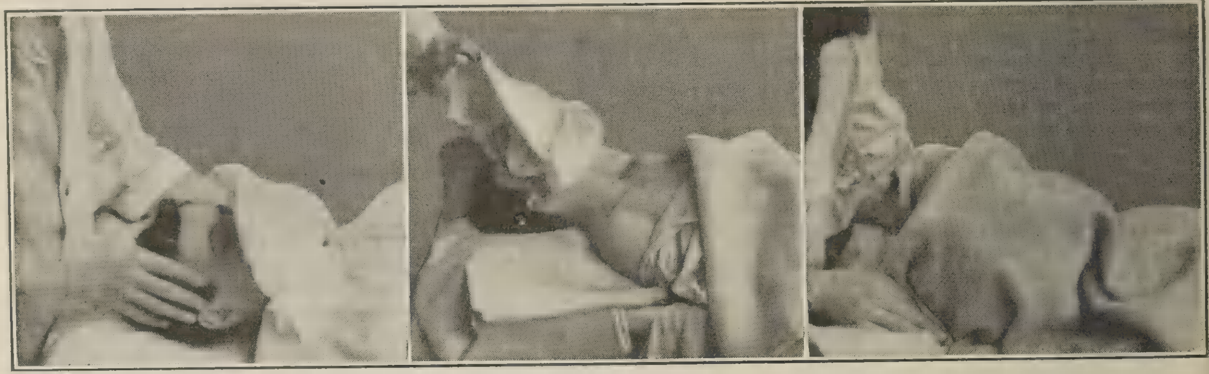
By light anæsthesia I do not, of course, mean a struggling patient. There is general muscular relaxation, the respiration is regular, but certain reflexes persist, the pharynx and larynx respond with a muscular contraction if stimulated. The patient can cough—and so can in this way protect himself from blood entering the air-passages—on the other hand, he can obstruct his own air-way by spasm of the cords. I assume that, before the administration of ether, atropin sulphate has been injected hypodermically. The contrast in the clinical picture of ether anæsthesia with and without this drug is too well known to need discussion.

---

[1] Abridged from a paper read before the joint sections of Anæsthetics and Laryngology of the Royal Society of Medicine on Feb. 6th.

An Alternative Method to the Use of Clover's Inhaler.

There are many ways of inducing anæsthesia with ether, but in order to obtain this deep type a method must be used which is capable of giving a high concentration of ether vapour. So a modification of the so-called open ether method has been devised. It consists of extemporising a bag from a towel as the anæsthesia progresses, and converting the open ether into a semi-closed method, practically into a Clover inhaler, but capable of giving more ether and without the disadvantage of the absolutely air-tight and possibly septic rubber bag. This method is extravagant both of gauze and ether—a whole 6-yard roll of gauze being used for each case, and from 6 to 8 oz. of ether according to the physique of the patient. But it produces in from 6 to 8 minutes a type of anæsthesia that I believe can be obtained in no other way. It requires, of course, some little practice to get the patient under quickly and quietly, and success depends upon a regular increase in the strength of the vapour, so that the patient is always inhaling the maximum percentage of ether that will pass the larynx without producing spasm.



Illustrating the concentration of the ether vapour. The patient is allowed to inhale ether from the open mask for the few minutes necessary to abolish consciousness. A bag is then gradually improvised from a towel, and finally the vapour is still further concentrated by means of some thick substance—a blanket has been used in the illustration.

Dr. H. G. Butterfield has kindly taken the photographs here given from actual cases. The first shows the commencement of anæsthesia. The gauze mask, soaked with as much ether as it will conveniently hold without dripping, is gradually lowered to the patient's face. The second shows how a bag is improvised by means of a towel, and the third how the percentage of ether is finally concentrated considerably by means of a thick substance—in this case to emphasise the point I have used a blanket, but of course a thick towel would do equally well.

Now, although this looks like asphyxiating the patient, the practical fact is that when the respiration becomes shallow in the deep stage of narcosis the patient, although most profoundly anæsthetised, is pink and rosy, provided always that the even regular rhythm of respiration has not been obstructed by a too sudden increase of the strength of the ether vapour during the induction.

Special Application to Oto-rhino-laryngology.

Operations upon the nose and throat stand out in marked contrast to all others, in that blood can pass directly into the air-passages. It is this fact that has hampered the operator, as it may lead to hurry, may obstruct the view, and may necessitate a sudden alteration in position of the patient. No abdominal surgeon is ever called upon to operate upon a rigid and vomiting patient, nor is he generally handicapped by the necessity for speed.

We are familiar with old conditions of operation upon the mouth for malignant disease, in which the surgeon worked at a disadvantage and in a great hurry upon a patient sometimes struggling, certainly coughing up blood at intervals, and in danger of suffocation. Gradual evolution in the operative and anæsthetic technique has now produced a quiet patient, some form of mechanical air-way, allowing the operator ample time and opportunity to control hæmorrhage resulting in a practically bloodless operation, and a clear field for surgical manipulation. This general surgical principle may be extended to nose and throat operations, and I hold that this may be done with complete safety with some slight alterations in traditional methods.

As the technique of anæsthesia differs so materially in different cases, it will perhaps be an advantage to classify them according to the conditions present. For practical purposes we may consider that operations upon the ethmoid, intranasal operations for drainage of the frontal sinus, removal of portions of the inferior turbinates, and operations for drainage of the maxillary antra—both the intranasal and the radical Colber Luck operation, have one feature in common: blood is introduced directly into the nasal cavities and so into the naso-pharynx, whilst at the same time the patient's head is raised. It is obvious that gravity will allow blood to find its way directly through the larynx into the trachea and lungs. It appears that there are three alternative methods of preventing the blood entering the larynx :—

(1) To use light anæsthesia and allow the patient to cough up his own blood.

This is generally effective, but has disadvantages. The amount of blood collecting in the pharynx may become great, necessitating the interruption of the operation in order to mop it out. Furthermore, I have seen blood sucked into the trachea even with a coughing patient.

(2) To shut off the nasal cavities from the pharynx by means of a well-fitting post-nasal plug—using at the same time one of the many forms of mechanical breathing tubes, of which Hewitt's air-way is a type, in the pharynx.

There is an objection urged against this procedure. It is said that a post-nasal sponge, by preventing the blood running into the pharynx and confining it to the nasal cavities, causes it to flow from the nostril, so obscuring the view of the operator. But although it may sometimes be an inconvenience, if the blood is not confined to the nasal cavities it will run through the posterior nares into the pharynx, possibly slightly adding to the danger of the operation however lightly the patient may be under; and, furthermore, it will certainly make the patient cough and by collecting will once more introduce the necessity for a speedy completion of the operation. The advantage gained by the opportunity of a leisurely completion of the operation, with a patient who is absolutely safe from suffocation, even if it does increase the amount of mopping through the nostril, outweighs the transitory gain of a few moments' clear view, accompanied by an increasing collection of blood in the pharynx, which may at any moment give rise to a surgical emergency.

(3) The third method of preventing blood entering the larynx in those operations where the patient is in the raised position is by using the intratracheal insufflation of ether.

That it prevents blood entering the air-passages is admitted; it maintains an even regular degree of anæsthesia—and a mechanically perfect air-way whatever the position of the head. It will be interesting and instructive to hear the opinion of those who have used this machine for these cases. Personally I think that for operations upon the maxillary antrum for malignant disease or even for the radical drainage operation it is almost ideal—but for the more delicate intranasal operations I have noticed that the return blast of air through the nostril churns up the blood and appears to cause the operator more inconvenience than a post-nasal plug. I have often used this machine in conjunction with a post-nasal plug, which prevents the air blowing through the nostril, but the apparatus is bulky for universal use in operations of this nature, and I think that the results obtained with a post-nasal plug and an air-way are equally, if not more, satisfactory.

Anæsthetic Technique in the Removal of Tonsils and Adenoids.

The next anæsthetic technique which I wish to consider is associated with the removal of tonsils and adenoids. I know that there is considerable difference of opinion upon this subject. It is apparent that the type and degree of anæsthesia to be used is intimately connected with the nature of the operation performed, and it is in this operation, I think, more than in all others, that a sympathetic coöperation between the operator and anæsthetist is essential in the interests both of safety and efficiency. I have said before that I personally believe ether should be used as the anæsthetic. That it is safer than $CHCl_3$ cannot be denied. That any degree of anæsthesia can be produced and continued with ether and ether only in the most vigorous adult is a fact that can be verified at any time.

There are, from the anæsthetist's point of view, two methods—one with light anæsthesia, the other with deep anæsthesia.

The first, which I will describe as the rapid method, consists in the removal of both tonsils with the reverse guillotine, the patient either lying on his back or sitting up. After removal the patient is quickly turned into such a position that the blood may drain out of the mouth. Some operators remove the tonsil with the patient lying upon the side.

In the second type of operation a profound degree of anæsthesia is used. Mechanical means are adopted to prevent the entry of blood into the air-passages. The tonsils are removed either by the reverse guillotine or dissection. All hæmorrhage is stopped before the patient leaves the table, as in other surgical operations. This necessitates a modification in the traditional position. It was found essential in the interest of safety that gravity should no longer carry blood into the air-passages. To adopt that general principle of operative surgery of the mouth that if the advantages of a deep anæsthesia, together with a quiet field of operation and opportunity for a leisurely performance, are to be enjoyed some mechanical means must be employed to keep blood out of the air-passages.

In the operation under discussion this is secured in a simple manner. The shoulders are raised upon a sand-bag. The head is allowed to fall back and rest upon the vertex in such a manner that the front of the chest, the front of the neck, and the chin are all in one straight line. This position places the larynx well above the field of operation and converts the naso-pharynx into a dependent receptacle. In this position, and only in this position, deep anæsthesia may be used either for enucleation by dissection or by the reverse guillotine. The surgeon has all the facilities for which he asks—a perfect view, ample time, an immobile field of operation, and every opportunity to stop hæmorrhage. The pros and cons of the different types of operation are entirely a surgical matter, but the question of safety of the various procedures is relevant to the subject under discussion. The originators of the method adopted the position widely used for similar operations, such as those for cleft palate and for removal of small parts of the tongue. These are essentially the same as tonsil operations, and the conditions are identical. The operations used to be performed with the head slightly raised, causing considerable discomfort to the anæsthetist, together with much mopping and coughing. But a cleft palate operation in the head back position presents no difficulty or danger; the surgeon sitting behind the patient has ample time and perfect vision for a somewhat tedious operation. An occasional mop prevents blood collecting in bulk in the naso-pharynx. The patient is under, with even regular respiration, the palate is still, there is no anxiety or difficulty for the anæsthetist.

It is the same thing with the tonsil operation. Carried out by two people who are conversant with the details I do not think it is too much to say that it is mechanically perfect, and that if blood does enter the larynx it is due to a failure of technique and not to a defect in the principle of the method.

The Anæsthetic in Examinations of the Larynx, Trachea, and Œsophagus.

Another group of cases in which the anæsthetic plays a considerable part comprises direct examination of the larynx, trachea, and œsophagus by means of tubes. It seems to me that a profound anæsthesia is essential for these cases, anæsthesia so profound that the cords stand abducted, even in the presence of a tube in the upper opening of the larynx. Spasm of the cords and contractions of the pharynx are the difficulties the operator has to contend with, and I do not think it is too much to say that some of the delicate intralaryngeal manipulations are impossible should this persistently occur. Again, I think ether is the proper anæsthetic to employ. It is sometimes necessary, especially with an irritable larynx, to push it to an extreme degree, almost to the cessation of respiration.

Finally, there are operations upon the larynx for the removal of intrinsic carcinomata. From the anæsthetist's point of view the conditions present are precisely the same as in cases of malignant disease of the upper opening of the larynx, pyriform fossæ, &c. The air-passages are more or less obstructed by a tumour. There may be stridor, and there is possibly definite respiratory obstruction. But here we have a very different state of affairs compared with most other operations upon the nose and throat. The cases are of a really serious nature. An anæsthetic must be given, possibly in the presence of obstructed respiration, in order that a preliminary tracheotomy may be performed.

Now, if ether is administered to these patients, the rise of blood pressure during the induction may cause slight swelling of the mucous membrane and completely occlude the already narrowed airway, with the result that we have an asphyxiated patient, an emergency tracheotomy upon a patient not properly under, much explosive coughing upon the introduction of the tracheotomy tube, with possibly the aspiration of blood and septic matter.

Therefore I think that $CHCl_3$ is undoubtedly the proper anæsthetic, because in the broad sense it is safer than ether in these special cases. A degree of anæsthesia must be maintained sufficiently deep to permit the tracheotomy tube to be introduced without producing reflex coughing, because pneumonia following aspiration of septic matter is a very definite danger, and a proper degree of anæsthesia will always ensure a peaceful tracheotomy.

Summary.

In summing up I may say I have endeavoured to uphold the safety of ether; the danger of $CHCl_3$ as demonstrated, apart from all scientific considerations, by the records of the daily press; the improvements in the methods of administering ether so that the congestion, cyanosis, and salivation of other days have given place to an anæsthesia which has all the merits and none of the dangers of chloroform; and the gradual evolution of operative surgery of the mouth, from the rapid operation and coughing patient towards the ideal of a quiet patient free from all risk of suffocation, combined with every facility for a thorough and deliberate operation.

The Gillson Scholarship for Research in Pathology.—The Society of Apothecaries has awarded the Gillson scholarship for original research in pathology, of the annual value of £105, to Dr. A. L. Urquhart, of St. Thomas's Hospital.

A CASE OF HIRSCHSPRUNG'S DISEASE,

CAUSING ACUTE OBSTRUCTION.

By I. TEWFIK, M.R.C.S.Eng., L.R.C.P.Lond.

The following case is of interest both from the point of diagnosing the condition, which is rare, and also from the point of being simulated by an acute obstructive condition which seldom manifests itself in cases of Hirschsprung's disease. The method adopted in the operative technique is to my mind the most suitable, as it alleviates the shock, and gives a chance to the affected colon to recover and decrease in size—two essential factors in the success of the anastomosis after the resection.

S. L., aged 10, was admitted to hospital on Oct. 27th, 1918, with symptoms of acute intestinal obstruction. Temperature 99° F.; pulse 120, rather feeble. He had been vomiting two days previously.

Previous history.—Five years ago he was admitted to one of the London hospitals, because "the child was always delicate, his stomach was getting bigger, and his bowels very constipated." Often his bowels did not act for a week or ten days. He was in hospital then for about six months with no apparent benefit.

Examination.—The child looked ill, with a furred tongue and the anxious expression indicative of an acute abdomen; his abdomen was protuberant and hard, especially in the lower half. On percussion a dull note was elicited over the greater part of the lower abdomen. The child otherwise looked quite normal.

Operation.—I decided to operate at once and the abdomen was opened through a right paramedian incision. The condition suspected was revealed straight away; in the abdomen was a reddish-blue mass which looked like a twisted ovarian cyst. The tumour really consisted of the descending and pelvic colons greatly distended and full of fæces; the colour was due to the stagnant fæces infecting the bowel wall. I decided to relieve the obstruction first and give the distended and infected diseased colon a chance to improve, and also to lessen the shock of the operation, a matter of vital importance. Through a left gridiron incision I brought out the proximal end of the descending colon, which was quite healthy, after cutting it away from the rest. The distal end was closed up securely with sutures and returned into the abdomen. By the help of my assistant, who dilated the rectum, I was able to empty the contents of the diseased colon. A Paul's tube was inserted in the colotomy. The child was infused through the axilla during the operation. Daily rectal washouts were given to disinfect the colon, which was obviously in an infected condition, and the child made an uninterrupted recovery. On Dec. 3rd I decided to complete the operation. The abdomen was opened through a left paramedian incision; subcutaneous saline infusion was given in the axilla. The diseased colon was found to have decreased in size and was in a much healthier condition. It extended far down in the pelvic colon, which made the resection and the subsequent end-to-end anastomosis rather tedious. The abdomen was closed in the ordinary way and a drainage-tube inserted through the old colotomy incision. Before closing the abdomen a stomach-tube was passed from the rectum past the anastomosis. The bowels acted regularly on the third day, and then daily afterwards till the ninth day, when fæces were noticed to appear through the old colotomy wound. The patient ran an irregular pyrexia for three weeks, beginning one week after the operation. His bowels still acted normally every day while the fæcal fistula was discharging, some days more than others. The fistula eventually closed entirely on March 27th, 1919, and remained closed till his discharge on May 19th. His bowels since the second operation acted normally and regularly every day; the child improved considerably, putting on weight, and looked altogether different. I have recently heard that his fistula broke down, but I presume it will soon close up again.

Rochester.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

WAR SECTION.

GAS POISONING.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 9th, when a discussion was opened by Sir WILMOT HERRINGHAM on Gas Poisoning. The paper appears in the present issue of THE LANCET.

Three Phases of Gas Warfare.

Dr. C. G. DOUGLAS divided gas warfare into three phases: (1) the attacks with gas clouds (chlorine and phosgene) liberated from cylinders in 1915 and 1916; (2) bombardments with shell containing "lethal" gases—e.g., phosgene and diphosgene—July, 1916, to July, 1917; (3) the mustard-gas period, July, 1917, to the armistice, when shell containing either mustard gas, lethal gases such as phosgene, or irritant organic arsenic compounds were employed. During the first two periods the number of gas casualties was by no means excessive, paying due consideration to the magnitude of the attacks and the nature of the gas used. The average mortality amongst the gas casualties was higher in the case of the cloud-gas attacks than in the bombardments with lethal gas shell, the difference being due in part to the progressive improvement in defensive measures against gas, and in part to the fact that gas-shell bombardments were a somewhat ineffective method of delivering the poisonous gas in comparison with the liberation of gas from cylinders. During the last phase of gas warfare mustard gas was responsible for most of the gas casualties, but though the number of gas casualties was large the mortality amongst them was extremely low. In the case of mustard gas, therefore, the main problem of the medical officer is to cope with the great number of gas casualties, and to endeavour to reduce the period necessary for convalescence by improvements in treatment so as to minimise the wastage of man-power. In chlorine or phosgene poisoning the medical officer's hardest task is to tide the case over the acute stage of pulmonary œdema during the first 48 hours after exposure to gas.

Histology and Pathology of Gas Poisoning.

Dr. J. W. MCNEE said he would deal with the subject in the way Sir Wilmot Herringham had suggested might be useful. During the whole period of the war his attention had been focussed entirely on the pathology of gas poisoning, but now it was interesting and important to try to correlate some of the late symptoms with what might be expected to result from the lesions found in the acute stages. He therefore proposed to sum up in a few words the main effects noted in acute cases of chlorine, phosgene, and "mustard-gas" poisoning; thereafter, to indicate the chronic changes which might be expected to follow in the severer cases; and finally, to refer to the actual symptomatology of men now receiving pensions for ill-health on account of gassing. He said that chlorine was a completely irrespirable gas, producing local irritant effects only in the respiratory tract, without any distal action. In the lungs the lesions were extreme disruptive emphysema and intense œdema. During the recovery stage bronchitis was of frequent occurrence. Any late effects might be expected to be due to the emphysema and to the bronchitis. Phosgene produced effects beyond the pulmonary system, in contrast to chlorine. Some of these effects could be studied histologically, but others had never been explained. Phosgene exerted some serious depressant action on the heart, and, in contrast to chlorine, sudden deaths from cardiac failure were well known. Moreover, "grey cases" were much commoner after phosgene than after chlorine. In the lungs phosgene gave rise to great emphysema (not so disruptive as with chlorine) and extreme œdema. The bronchial mucous membrane was little affected, unless sepsis was added, as was common, in the stage of recovery. Another change noted was the occurrence of hyaline thrombosis in the pulmonary capillaries, and thrombosis was also observed in some instances in the glomerular capillaries of the kidneys, and in the capillaries of the white matter of the brain. In the last position the thrombosis was associated with multiple small hæmorrhages. Any late effects of phosgene poisoning might be expected to be due to the pulmonary emphysema, to the effect on the heart, noted clinically, but of unknown ætiology, and perhaps to some of the other distal lesions which have been noted. Mustard gas induced lesions of quite different character from the other two gases. The changes in the lungs were alone of importance for late effects. After a period of incubation (accounting for the absence of deaths on the first day, as shown on Colonel Douglas's chart), necrosis of the mucosa of the trachea and larger bronchi took place, followed by the pouring out of a fibrinous membrane very similar to the membrane in diphtheria. This fibrin afforded suitable nourishment for micro-organisms, the abundant growth of which induced intense septic bronchitis, and often broncho-pneumonia, &c. Œdema and emphysema were not features of mustard-gas poisoning. The late effects might be expected to result almost entirely from the extreme damage of the walls of the trachea and bronchi. The speaker then referred very briefly to some of the symptoms complained of by pensioners. They agreed closely with those to be expected from a study of the acute lesions, consisting chiefly of recurrent bronchitis, breathlessness, and tachycardia. Physical signs to account for the symptoms were not readily elicited. Reference was also made to the condition studied by the French writers, Achard and Flandin, who have described a "pseudo-tuberculosis" associated with purulent sputum and ill-health, but where tubercle bacilli could never be demonstrated in the sputum. They ascribe the symptoms to a fibrosis of the tissues surrounding the bronchi.

Dr. McNee passed round a specimen showing multiple small circular cerebral hæmorrhages.

Tribute to Scientific Workers.

Colonel S. L. CUMMINS paid a warm tribute to the work of the late Professor W. Watson, and of Professor J. S. Haldane, Professor H. B. Baker, Captain C. G. Douglas, Captain Mouat Jones, and Captain S. J. Auld, whose "magnificent services were instrumental in bringing anti-gas defence to the high state of efficiency which was ultimately attained." He considered that Sir William Horrocks "accomplished miracles in producing in the shortest possible time the vast number of masks, helmets, and respirators that were required by the armies in France." Colonel Cummins went on to say: "It was soon evident that anti-gas defence was not a medical service, *not* a service of the kind that should work under the Adjutant-General, but a branch of warfare affecting the integrity of the battle-line; obviously a function of the General Staff. The Gas Directorate was formed under the command of General Thuillier, R.E., in which Colonel Foulkes, while retaining command of the Special Brigade, served as Assistant Director of Gas Services for Offence, while I was appointed Assistant Director for Defence. In this way a great service for gas warfare in all its branches came into existence, and its subsequent history is bound up with the general history of the war. But while I hold strongly that gas warfare in its defensive as well as its offensive aspects must be a function of a special force of scientific soldiers working under the General Staff, I hold equally strongly that the medical and physiological organisation for dealing with gas cases and investigating the effects of gases must be under the Director-General of the Army Medical Services. The knowledge gained by such an organisation is essential to the Director-General and also to the General Staff—to the one in order that everything possible may be done for gas casualties; to the other because it is necessary to know the effect of gases on man and animals when the question arises of which gas to use against the enemy."

Therapeutic Value of Bleeding.

Professor J. S. HALDANE, F.R.S., considered that clinical evidence was of even greater value than laboratory experiments, and he held the opinion that bleeding was of very considerable therapeutic value in those cases of blue asphyxia with engorgement of the veins, as high venous blood pressure favoured the development of œdema of the lungs. The blueness was simply due to anoxæmia, and there was no decomposition of the hæmoglobin. In "grey" cases with no distension of superficial veins obviously no benefit from bleeding was to be expected. Blue asphyxia was more common in the immediate cyanosis following chlorine gassing and grey in the delayed œdema of the lungs following phosgene gassing. To reach the blood the oxygen has to pass through the delicate layer of alveolar epithelium and capillary wall which separates the blood from the air, and the reason why the blood was not properly oxygenated in gas cases was presumably that with the swelling and exudation, and paralysis of secretion by injury to the cells, the oxygen could not get through to the blood quickly enough to saturate it to the normal extent. He considered that the second, and by far the most effective, means of treatment is the administration of pure oxygen in a suitable apparatus. In chlorine cases, owing to the bronchitis, emphysema, and corresponding areas of relative collapse, there is probably an excess of CO_2 in the arterial blood, while in the phosgene cases there is no such excess. In any case the symptoms, apart from the local signs of œdema of the lungs, resemble those of the uncomplicated anoxæmia of very high altitudes.

Sir **WILMOT HERRINGHAM**, in reply, opposed Colonel Cummins's opinion that anti-gas defence was a function of the General Staff. On the contrary, he considered that no scientific work in a medical sense should be under the General Staff, as their knowledge of even elementary science was often so limited as to be humorous to a medical man, and he proceeded to illustrate this by several anecdotes, the truth of which he guaranteed.

CLINICAL SECTION.

EXHIBITION OF CLINICAL CASES.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 13th, Sir **ANTHONY BOWLBY**, the President, being in the chair, when there was an exhibition of clinical cases.

Thrombo-angeitis Obliterans.

Dr. **W. SALISBURY-SHARPE** showed a case of Thrombo-angeitis Obliterans in a male Jew aged 23 years. There had been constant pain, worse at times, both in the hands and feet, and destructive changes had led to the loss of part of the ring and little fingers of the right hand, of the corresponding fingers of the left hand, and of several toes. The disease had started at 3 years of age. Radiograms showed, in addition to the loss of the ungual phalanges and of part of the middle phalanges in the affected digits, rarefactive changes, more marked in the feet than in the hands.

Dr. **F. PARKES WEBER** said that in this case the pulsation in the dorsalis pedis artery in both feet was very good, and that fact in itself, in his opinion, was sufficient to negative the diagnosis of thrombo-angeitis obliterans. He showed the same patient before this section on Nov. 14th, 1913, as an example of angiokeratoma with bony changes.[1] The patient was then aged 16 years, and since the age of 4 had suffered from chilblains on the hands and feet and pinnæ of the ears, which had left a good deal of scarring. The Wassermann reaction was negative. He remarked at the time that the chilblain condition ordinarily associated with angiokeratoma of the hands and feet seemed to be insufficient to account for the bony changes revealed by X ray examination.

Sir **JAMES GALLOWAY** said that angiokeratoma was not usually so severe, and he had never seen the bony changes in connexion with it. He favoured the original diagnosis.

The **PRESIDENT** pointed out that the feet and hands were warm and not cold and blue, as would be expected in circulatory defects.

Mr. **N. C. LAKE** spoke of a case of thrombo-angeitis obliterans in a Polish Jew, aged 36, for whom it had been necessary to amputate through the centre of the thigh. He was a tailor and a heavy smoker. The Wassermann reaction was negative. The main arteries were seen to be about half the normal size. Sections of the popliteal and of the anterior and posterior tibial arteries were shown.

Unilateral Sweating of the Face.

Dr. **G. DE B. TURTLE** showed a case of Unilateral Sweating of the Face, which was previously shown before the section at the December meeting. The man had since developed a paresis of the external rectus of the right side, producing diplopia. A Wassermann reaction was negative, but there was a definite history of syphilis contracted some 20 years ago. He had therefore been treated with antisyphilitic remedies with considerable improvement, and at the same time the sweating had diminished; the case was again brought before the section in view of a possible connexion between the two conditions.

Unilateral Dwarfism of Limbs.

Dr. **PARKES WEBER** showed a case of Unilateral Dwarfism of Limbs connected with Congenital Chondromata. It was not generally recognised, he said, that the presence of congenital chondromata in long bones might be in some way causally connected with dwarfism of the limbs in question. The patient was a healthy boy, aged 13 years, whose only abnormality was that his right limbs were abnormally short and somewhat deformed. From the acromion to the tip of the styloid process of the radius measured on the right side 35 cm., on the left side 45 cm. From the great trochanter to the tip of the external malleolus on the right side the measurement was 50 cm., on the left side 67 cm. Skiagrams taken in January, 1920, showed the presence of a large chondroma at the lower end of the right tibia and of chondromata in the right ulna and right radius. There was bending of the right fibula, doubtless due to pressure from the tibial chondroma. There was no history of any similar condition in the patient's family. According to the mother nothing abnormal was noticed in the patient at the time of his birth, except a peculiar mottling of the skin of the right upper and lower extremities. The shortening of the right limbs was not observed until the boy was 1½ years old. One or two orthopædic operations had been attempted. In January, 1920, there was a fracture of the right forearm from a fall. An almost exactly similar case in a boy, aged 6 years, was recently shown at the Section for the Study of Disease in Children by Mr. J. E. Adams as a case of shortening of the limbs on one side of the body.

Myxœdema with High Blood Pressure.

Dr. **PARKES WEBER** also showed a case of Myxœdema with High Blood Pressure, preceded by enlargement of the thyroid gland. The patient, a woman aged 55½ years, had still the typical appearance of myxœdema, but, under thyroid treatment lately, she had been losing in body weight, and her face had become thinner, whilst her speech was quicker, and she was less sluggish in her mentality. Her symptoms had commenced about seven years ago, rather more than a year after her menopause. She at first complained of a feeling of stiffness in her feet. The thyroid gland was observed to be enlarged six years ago, and it was still decidedly large, but appeared smaller than it had been. There had been no symptoms of Graves's disease. She complained much of a kind of acroparæsthesia in her fingers and toes. The Wassermann reaction was negative. More observations were required with regard to the blood pressure in cases of myxœdema. In the present patient the brachial systolic pressure was 210–240 mm. Hg.

Pityriasis Rubra Pilaris.

Dr. **PARKES WEBER** also showed a case of Pityriasis Rubra Pilaris (generalised form). The patient, aged 54 years, was a strongly built man. His case was a typical example of generalised pityriasis rubra pilaris (Devergie), the "lichen ruber acuminatus" of Kaposi. The disease commenced in October, 1919, with itching all over his body. On the previous night he had partaken of sardines and brandy. During the two preceding years he had suffered a good deal from dyspeptic pains. The eruption was of the characteristic grater or goose-skin type on the trunk and upper extremities, and there was diffuse keratosis on the palms of the hands and on the feet and legs. On the scalp the eruption had a somewhat seborrhœic appearance. The patient was apparently improving. He had lately been treated by thyroid extract, liq. arsenicalis, and an alkaline sodium salicylate mixture, with hot baths for the pruritus.

---

[1] Proceedings of the Royal Society of Medicine, Clinical Section, 1913–14, vii., p. 25.

Mr. R. P. ROWLANDS showed a case of

Gastro-jejuno-colic Fistula.

A gastro-jejunostomy had been performed by another surgeon for symptoms of duodenal ulcer. A year and a half later there had been a second operation for suppurating appendicitis and three years later gastro-jejuno-colic fistula followed, with acid diarrhœa, vomiting, eructation of foul gas, and wasting. X ray examination showed that the gastro-jejunostomy opening was too high, but failed to disclose the opening from the colon to the stomach. A barium enema, however, and subsequent X ray examination, showed the presence of barium in the stomach contents. At the operation the gastro-jejunostomy opening was not small, but the proximal limb of the jejunum was six inches long and greatly distended. Now, four and a half years later, the patient was practically well. Gastro-jejunal ulcer followed gastro-jejunostomy in about 1·4 per cent. of cases, but gastro-jejuno-colic fistula was much rarer. He had only seen three examples and only one of the patients was alive. In one of these the fistula communicated also with the ileum. In two-thirds of the cases of ulceration following gastro-jejunostomy the ulcer was in the jejunum; in one-third at the gastro-jejunal ring. In these colic cases it was in the ring. He emphasised the need for care and suitable dieting of patients after gastro-jejunostomy had been performed, a care which should extend over two to three months.

Dr. WILFRED HARRIS showed a case of

Bilateral Destruction of the Gasserian Ganglia by Alcohol Injection for Chronic Trigeminal Neuralgia.

The patient, a woman aged 49, began to suffer 15 years ago from spasmodic pains on the right side of the face commencing in the upper jaw and spreading to the lower jaw and temple. At first there were remissions of the pain, perhaps for a few months, but the spasms became more frequent and severe in the latter part of 1912, the pain occurring every few minutes and keeping her awake. With the neuralgic spasms she used also to have well-marked right facial spasm, with the exception of the oral muscles and the platysma, and by rubbing the skin of her face during the paroxysms of pain she had rendered that of the lower portion of the cheek and chin on that side almost horny, and had rubbed away the outer half of the right eyebrow. Early in 1913 she had been admitted into hospital, and at that time had no teeth in either right jaw; the sensation of the face was perfect, with no true hyperæsthesia, though she was afraid of light touches starting the painful spasm. In February, 1913, at the late Dr. F. E. Batten's request, Dr. Harris had injected the right foramen ovale under chloroform, by the usual route beneath the zygoma, using 1·75 c.cm. of 80 per cent. alcohol. As a result she had complete right fifth nerve paralysis, motor and sensory, with loss of taste on the anterior two-thirds of the right side of the tongue. Slight keratitis developed after a week, and the eyelids were sewn up for six months. After opening the eyelids again it was seen that the cornea had remained perfectly healthy. There had been no return of neuralgia on the right side and the anæsthesia had remained permanent and complete. The motor root, however, recovered, so that the right masseter, pterygoids, &c., recovered well. Five and a half years later, in August, 1918, there was a recurrence of neuralgia on the left side in the cheek and upper jaw. She stated that she had had "a queer feeling" in the cheek for some months, but no pain until July, when a severe twinge seized her in the upper gum, spreading into the temple and side of the nose. A touch on the lower lip, talking, or eating would start it. Examination showed that the right fifth area was totally anæsthetic, with right-sided loss of taste as before, though the masticatory muscles had recovered fully. He then injected her left foramen rotundum with 90 per cent. alcohol, using the route in front of the coronary process behind the antrum and through the pterygo-maxillary fissure. Fairly deep anæsthesia of the second division of the fifth was produced, and she was free from neuralgia until November, 1919, when it recurred after 16 months. In December it was decided to destroy the left Gasserian ganglion by alcohol injection, in order to give her permanent relief. This was a feasible operation owing to the recovery of the right masticatory muscles, though bilateral gasserectomy was an impossible operation owing to the permanent jaw drop which would be produced from the destruction of the motor branches of both fifth nerves. Using novocaine anæsthesia only, he injected the left Gasserian ganglion with 90 per cent. alcohol, and produced total left fifth nerve palsy, motor and sensory. The left eyelids were closed with strapping at once, and by washing out the conjunctival sac twice daily for ten days the cornea had remained quite healthy. At present there was total anæsthesia of the whole of the front half of the head and face owing to the bilateral ganglion destruction, and she could taste nothing at all until she began to swallow, when she appreciated taste quite keenly. There was no perception of taste whatever on the front portion of the tongue, but she could at once recognise salt, sweet, or bitter with solutions placed on the back of the tongue or fauces. The case was a good illustration of the undoubted fact that in the majority of subjects taste sensations are conveyed to the pons from the anterior two-thirds of the tongue by the fifth nerve and not by the pars intermedia Wrisbergi, the so-called central prolongation of the chorda tympani.

Dr. S. A. K. WILSON, in congratulating Dr. Harris on the result, pointed out the obvious practical advantage of the method over double gasserectomy. There was clearly no loss of muscle sense, and it appeared that the muscle afferent fibres must run in the seventh nerve.

The PRESIDENT said that several years ago he had seen a young officer suffering from causalgia following injury of the median nerve. As the result of a small injection of alcohol the pain went, but after three years there was still loss of motor power. He asked what was the experience of neurologists with regard to injection of a mixed nerve.

Dr. HARRIS, in his reply, stated that he had had some experience of injection of mixed nerves during the war, and had found that complete destruction had been necessary to banish the pain. Recovery of motor function during the time that they were under observation had not been satisfactory.

Dr. WILSON showed two cases of

Symptomatic Paralysis Agitans following Encephalitis Lethargica.

The first was that of a girl, aged 17, who in February, 1919, had influenza. A week later nocturnal delirium was followed in the morning by diplopia and headache, stiffness and weakness in the arms and legs. Two days afterwards ptosis, lasting three weeks and lethargy lasting two months, supervened. The memory was good for events which happened during this state. Rigidity began while she was in bed, and increased for a time after she got up. She could neither walk nor eat quickly. Involuntary movements of the jaw and left arm occurred during the early part of the illness; those in the jaw persisted. When shown, the cerebration and memory were normal. Phonation was weak and monotonous, and articulation slow. Special senses normal. The pupils were central and circular, and there were spontaneous nystagmoid movements and slow punctate lateral deviation of the eyes, but no diplopia. Slight trismus was present and involuntary chewing movements of the jaw, but there was no sensory loss over the distribution of the fifth nerve. The face was symmetrically immobile, with a spastic smile. There was some spasticity of the tongue. Sensation was not impaired. General rigidity was accompanied by a maintenance of the upper limbs in the attitude of Parkinson's disease. There were no involuntary movements other than those of the jaw, but there was slight tremor of the right hand. The gait and general attitude were that of marked Parkinson's disease. Knee-jerks were obtained with difficulty and ankle-jerks were absent.

In the second case, that of a man over 20, encephalitis lethargica occurred in December, 1918. The symptoms gradually disappeared and the patient's condition became that of a typical symptomatic paralysis agitans. Dr. Wilson said that recent work had shown that the lesion of paralysis agitans was situated in the corpus striatum and subthalamic region. He could only suppose that the effects of encephalitis lethargica reached to the depth of these regions.

Dr. WILSON also showed a case of

? *Polyneuritis Cranialis.*

The man, aged 50, complained first of pain in the right ear and tenderness over the mastoid in September, 1918. Two weeks later he developed broncho-pneumonia, with unconsciousness for some days. On recovery of consciousness the pain had disappeared, but he was deaf in the right ear and the right face was paralysed and "dead." He was unable to swallow and was nasally fed for eight weeks. There were headache in the parietal region and occasional vomiting after food. Diplopia was present, but vision was otherwise good. The right shoulder ached and was wasted. His speech was whispering. Since then swallowing had improved, but fluids occasionally regurgitated through the nose, and he could not swallow solids. Phonation was better, but not normal. There was occasional bi-temporal headache. Vision had deteriorated, especially in the right eye, but the diplopia had diminished. There was some weakness of the sphincters. At present the sense of smell was greater on the right side than the left. Taste was lost. Middle-ear deafness was present on the right side. The visual fields were normal and visual acuity good. With regard to the other cranial nerves, there were hypoæsthesia to touch and pain over the middle division of the right fifth, weakness of the right external rectus with diplopia on looking to the right, complete paralysis of the right seventh with wasting, paralysis of the right constrictors of the pharynx with "curtain movement" of the pharynx from right to left, right hemi-palsy of the larynx with defective phonation and paralysis of the right half of the palate, paralysis and wasting of the right sterno-mastoid and trapezius muscles, and paralysis, wasting, and fibrillation of the right half of the tongue, with paresis and slight wasting of the left half. Dysarthria was also present. All the cranial nerves on the right side from the seventh to the twelfth were affected.

A Case of Nerve Disease for Diagnosis.

Dr. J. WALTER CARR showed a case of Nerve Disease for diagnosis. The patient was a boy, aged 8, whose present illness began insidiously in June, 1919, with unsteadiness of the legs in walking and some loss of strength in the left arm. He had been getting gradually worse since. There was no headache or vomiting. He was now unable to stand or walk on account of the persistent tonic spasm of the right leg, leading to flexion of the hip and thigh and extreme extension and inversion of the foot, which was in the position of pes cavus. The left leg showed a much slighter degree of spasm. The spasm persisted during sleep, relaxed under anæsthesia, but returned before consciousness was regained. The plantar reflexes were difficult to obtain, but were probably flexor. In the left arm there was some muscular spasm (increased by attention) and slight weakness. The boy did not use it much. The right arm appeared to be normal. There was some weakness of the back muscles, with a tendency to lateral curvature of the spine. The tongue could not be protruded for more than about half an inch, and speech was very blurred and indistinct. Sensation was probably unaffected. The boy had lately had occasional loss of control over the sphincters and his intelligence was perhaps not quite up to the normal for his age. There were no ophthalmological changes. The Wassermann reaction was negative both in the blood and cerebro-spinal fluid; the latter fluid was normal in all respects.

Mr. A. H. TODD showed a case of Sarcoma of the Clavicle in which the whole clavicle had been removed. The man suffered from no disability.

Dr. H. BATTY SHAW showed a case of

Malignant Endocarditis Affecting the Pulmonary Valve.

The patient, a youth aged 16½ years, had been admitted to hospital with a history that he had been troubled with "heart complaint" for two and a half years, his symptoms being palpitation and shortness of breath on effort. Previous to that he had had no illnesses of any kind. On admission to hospital in December, 1919, he stated that he had developed pain over the heart during the previous four days. His mother was said to have had consumption, but was now well again; his father, brother, and two sisters were quite well. While in the hospital he had had fever almost continuously of a remittent and intermittent character, the maximum being 104° F.; the pulse varied from normal to 120, and the respiration from 24 to 30. He had always been of pale complexion, and during his stay in hospital had lost weight, being now 2 st. under weight. The blood examination showed secondary anæmia, and 5500 leucocytes per c.cm., the polymorphonuclear cells numbering 75 per cent. Cultures from the blood on two occasions had shown the presence of a *Streptococcus longus*. The spleen was enlarged and tender; blood had been found in the urine on one occasion and there were pain and some râles and rhonchi in the right axilla. A loud systolic murmur was heard over the pulmonary area, and there was a distinct systolic thrill in the same position conducted towards the left clavicle. From the facts that cardiac symptoms had only been noted during the last two and a half years, and that there was no cyanosis or clubbing of the fingers, the conclusion was drawn that the narrowing of the entrance of the pulmonary artery was due to malignant endocarditis of the valves, and that the case was not one of malignant endocarditis developing on valves damaged by congenital heart disease.

Sir JAMES GALLOWAY referred to a case which he had seen of malignant endocarditis of the pulmonary valve in which, post mortem, an old infective periostitis of the tibia had been found; and to another case of pulmonary valve infection in a child with no discovered primary focus.

COMBINED SECTIONS OF ANÆSTHETICS AND LARYNGOLOGY.

ANÆSTHESIA IN THROAT AND NOSE OPERATIONS.

A COMBINED meeting of these sections of the Royal Society of Medicine was held on Feb. 6th, Dr. LLEWELLYN POWELL, the President of the Anæsthetics Section, being in the chair, when Dr. F. S. ROOD opened a discussion on Anæsthesia in Throat and Nose Operations. An abstract of the paper is given in the present issue of THE LANCET.

Discussion.

Mr. HERBERT TILLEY said he had only congratulations to offer to Dr. Rood. The prime consideration in the choice of anæsthetics was always the safety of the patient, the second being the convenience to the surgeon. He thought it was indisputable that ether was safer than chloroform, and safer than any mixture of which chloroform formed part. He spoke of some cases in which anæsthesia was induced for the purpose of some trivial operation in a healthy subject, and death occurred before the operation was even commenced. If the substance was chloroform one never knew when such an accident might occur. Some, while agreeing that ether was the safer anæsthetic, considered there was more bleeding under it. If ether were given in the way Dr. Rood had just described there was a little more oozing during the operation, but it occurred while the surgeon was on the spot to stop it; the surgeon should not allow a patient off the table until all bleeding, except capillary oozing, had ceased. With chloroform there was little bleeding at the operation, but it might come on later when the surgeon was not within call.

Dr. D. W. Hill contended that Dr. Rood's method of administration was not correctly described as the "open ether method." Moreover, a means which required eight minutes for induction was not suitable for a busy out-patient department where many adenoid and tonsil cases had to be attended to. He spoke of the rapid and safe anæsthesia produced by ethyl chloride for these cases; he had seen only one case of critical difficulty under it.

Dr. G. A. H. Barton said he had been agreeably surprised to find how well patients did under Dr. Rood's method of giving ether for the enucleation or the dissection of tonsils. By using a little ethyl chloride at the commencement to stimulate the breathing, and abbreviate the period of resentment felt by some patients, and following on with ether, he got the requisite degree of anæsthesia quicker than the eight minutes mentioned by Dr. Rood. For endo-laryngeal surgery it was difficult to administer the anæsthetic through the air-passages. Failing a sufficiently deep narcosis in these cases he inclined to the use of rectal anæsthesia.

Sir StClair Thomson said anæsthesia for operations on the nose, in which blood could be prevented from descending into the air-passages by post-nasal sponges, differed little from other operations. The real anxiety occurred in operations on the pharynx. In the three fatalities he had had, neither the operator, his technique, nor that of the anæsthetist seemed to account for the death. He described the cases. In all, an independent opinion declared status lymphaticus to have been present. Ether was mostly given in America, but one distinguished New York operator had gone back to chloroform, and Dr. Chevalier Jackson carried out his endoscopic operations without any anæsthetic whatever. Sir StClair Thomson had seen a foreign body in the bronchus removed by him from a boy, aged 10, without any anæsthetic.

Dr. J. F. W. Silk discussed the question of the posture; the dependent position of the head, thrown well back, with a pillow under the shoulders, he thought was not in all ways good. Sir StClair Thomson's method of sitting the patient quite upright seemed to have many advantages; the blood flowed out of the nose and mouth, and had no tendency to go into the air-passages. Those who objected to ethyl chloride objected to the bag, not to the anæsthetic; when the bag was used the fatalities from this anæsthetic had been considerable. The induction time of ether could be reduced by adding about 3 per cent. of chloroform; and the consumption of ether was also considerably less. He showed a Kuhn's intubation tube, which rendered induction easy for throat operations.

Mr. W. Stuart-Low referred to the importance of the preparation of the patient, and emphasised especially the need of having a warm room for him. Very few deaths occurred under anæsthetics in India, and that was probably due to the warm climate ensuring operation patients against chill. He advocated operations in the morning, while the patient was fresh, and said there should be absolute silence in the operating theatre, if only that the anæsthetist could listen attentively to the respirations. He had great faith in chloroform, and he had not had a fatality in a young person for 30 years.

Dr. P. Watson-Williams said he would have liked to have heard discussed the advisability of giving morphine or scopolamine and morphine in conjunction with the other anæsthetics which were mentioned. And very little had been said about the blocking off of nerves by the injection of branches of the fifth, which had been carried out at Bristol with considerable success. He considered ether the best anæsthetic for operations on the respiratory tract, and referred to a case in which, after chloroform had been given, there was almost a fatal end. He did not think ether increased the liability to hæmorrhage, nor, if given slowly by the drop-bottle method and not pushed, did it result in much bronchial secretion. Hooper, of Boston, showed that during ether anæsthesia the adductors went first and the abductors last. During forced respiration expiration was slow, owing to medullary impulses, and if there was paralysis of the adductors there was a lessening of the influence of those pulse-slowing factors from medullary impulses. That seemed to be one of the reasons why the cardiac action was less inhibited during ether anæsthesia than during that of chloroform. Operations on the upper respiratory tract meant a pronounced influence on the fifth nerve, and there was likely, therefore, to be more cardiac inhibition than in operations on any other part of the body. He and his Bristol colleagues regarded ether as the ideal anæsthetic for operations on the upper respiratory tract.

Sir William Milligan said that, having been trained in Scotland, he had had a leaning towards chloroform during the whole of his surgical career, and he had had very little reason to regret it. No operation should be considered as a trivial one; each one, however slight, should be regarded as important. He agreed with Mr. Stuart-Low that operations, except those which were absolutely urgent, should be done in the morning when the patient was in his best condition. In such a discussion as this each participant should frankly give his own experience. He had a quite open mind as to the particular anæsthetic which should be used; he practically never interfered with the anæsthetist; the important need was for anæsthetist and operator to understand each other's idiosyncrasies. He was pleased to hear Dr. Silk's remark about Kuhn's intubation tube; he had heard it derided among experts, but he had used it on all possible occasions for the last ten years, even when operating on the nasal septum. But when gauze was taken out of the mouth the blood clot must be removed, or it might be sucked into the trachea. Adrenalin was a very dangerous drug to inject into the body when a general anæsthetic was being used. When ether was used for his cases he always insisted on a preliminary injection of morphia and atropine; under those conditions he had never been seriously troubled with hæmorrhage. He had never yet had, nor seen, a death under an anæsthetic.

Dr. H. E. G. Boyle said ether should not be regarded as the only anæsthetic for nose and throat operations. For two years he had been employing a combination which had three variations. Patients were given a hypodermic injection beforehand, and the anæsthesia was produced by nitrous oxide in conjunction with either ether, C.E. mixture, or, in some cases, chloroform—the latter in cases in which the surgeon was using the diathermic cautery. He had used the method for 590 cases, and those he had instructed added 155 administrations. The hypodermic injection varied in quality and quantity according to the requirements of the particular case. Deep anæsthesia was maintained by the endo-buccal or the endo-pharyngeal method, and needed but little of the drug. The induction by this method was pleasant to the patient, and there was no struggling or undesirable sequelæ.

Mr. Harold Barwell considered that ether, given by modern methods, preceded by atropine injection, was, on the whole, the best anæsthetic for nose and throat operations, especially when obstruction existed. In post-nasal resections he thought the post-nasal plug constituted an embarrassment to the surgeon, and it was unnecessary if the required ischæmia were obtained beforehand by injecting, 15 minutes before the operation, 1 in 10,000 or 1 in 15,000 adrenalin submucously. For such conditions as a suppurating maxillary antrum he preferred the patient to be lying on his side; he had never seen a case of pneumonia after anæsthesia when that posture was adopted.

Dr. A. Brown Kelly said that for prolonged operations he left the choice of the anæsthetic to the anæsthetist, who usually employed chloroform. For brief operations he strongly preferred bromide of ethyl, which he had used 25 years, in many thousands of cases.

Dr. Z. Mennell preferred to commence with gas and oxygen and then pass on to ether. That was quite safe so long as no chloroform was added, though it was very tempting to make that addition.

Dr. CECIL HUGHES referred to narcosis of moderate degree, which, having been commenced with either ether or gas and ether, could be best maintained with chloroform. There seemed then to be less after-sickness.

Dr. DUNDAS GRANT agreed that chloride of ethyl was a good anæsthetic for adenoid and tonsil operations on children, though sometimes he had wished for its longer duration.

Dr. W. J. MCCARDIE (Birmingham) described a method of induction of anæsthesia for nose—especially septal—operations, introduced by Dr. Seymour Jones, of Birmingham. It was known as the gauze curtain mask. Ether is given and the mouth tube inserted; a towel is placed round the patient's head and brought well over the cheeks; the mouth area is well vaselined and the gauze curtain strapped over the lips. The anæsthetic is then dropped on to the gauze over the mouth. He had himself used it with great satisfaction in more than a hundred cases.

Mr. W. DOUGLAS HARMER hoped Dr. Boyle's method would be specially discussed on another occasion.

Dr. HUGH PHILLIPS spoke highly of Dr. Boyle's method. He referred to a recent fatal case under ether administration in a child. The post-mortem examination revealed a thymus weighing 2¾ oz.

Dr. F. E. SHIPWAY declared that he had found very little danger from chloroform in his own practice if breathing was not obstructed.

Dr. ROOD waived his right of reply.

MEDICAL SOCIETY OF LONDON.

THE CLINICAL DIAGNOSIS OF DIPHTHERIA.

A MEETING of this society was held on Feb. 9th, Mr. V. WARREN LOW, the President, being in the chair, when Dr. H. DRINKWATER read a paper on the Clinical Diagnosis of Diphtheria and other Diseases of the Throat. In his opinion the differential diagnosis of diphtheria, except from Vincent's angina, could be settled by the appearance of the throat alone. There was a naked-eye character which he thought was constant. In every case sent into the East Denbighshire Fever Hospital as diphtheria over a period of three years the naked-eye diagnosis had been checked by a bacteriological examination, and without exception the bacteriological examination had confirmed the naked-eye diagnosis and proved the correctness of his views. The term "diphtheria" was applied, he said, to those cases only in which the Klebs-Löffler or the Hoffmann's bacillus was present. For convenience he divided the fauces into three areas on each side of the mid-line: the tonsillar area, the uvular area, and the palatal area. In diphtheria there might be five or six patches but never more than one patch in any one area. He had never met with a single exception to this rule, from which, if established, it followed that if in a given case two or more distinct deposits were seen in one tonsillar area the disease was not diphtheria, and the services of a bacteriologist were not required except for confirmation of the naked-eye diagnosis. It was of the utmost importance that the *whole* tonsillar area should be seen, for he had several times found two or more patches on a tonsil directly after having been told that there was only one. When two or more patches were present on one tonsil or in one tonsillar area the disease was generally follicular tonsillitis or influenza. If in a given case of membranous deposit on the fauces the patch was raised above the level of the mucous membrane, had sharply defined edges, and was single in each affected area, there could be no doubt that the disease was either diphtheria or Vincent's angina.

The features of diphtheria as manifested in the fauces in the early stage were a raised membranous deposit with sharply defined edges; the colour might be glistening white, bluish, yellow, or spotted with black or red; it rarely had the "wet wash-leather" appearance described in text-books; there was only one patch in any one area. These appearances were characteristic of the disease in the period of growth; after resolution had begun and the membrane was being cast off a number of isolated islands might be seen in the tonsillar area, but the diagnosis should have been made before this stage was reached. In many cases it was impossible to differentiate between Vincent's angina and diphtheria, as the distribution of the patches in both diseases was precisely similar. Occasionally a case of Vincent's angina could be recognised owing to certain peculiarities, the most characteristic of which was a sharply defined penetrating ulcer generally in the middle of the patch and running vertically. Sometimes, though rarely, the deposit did not go beyond the margin of the ulcer. Another peculiar feature was the marked thinning of the lower part of the patch, so that the inferior limit was ill defined. If either of these features were present the condition was recognised as Vincent's angina, however closely it might simulate diphtheria in other respects. Later on there was sometimes seen considerable erosion of the uvula, but this was long after the diagnosis should have been made.

Sometimes the deposit was softer and more creamy than that of diphtheria, but in other cases it was extremely dense and tenacious. Vincent's angina might be said to mimic diphtheria, just as hysteria and syphilis mimicked other morbid conditions.

In follicular tonsillitis there were marked swelling and congestion of the tonsils, and pus or muco-pus could be seen oozing out of several follicles. The single patch was never seen. In influenza also the patches were multiple in the tonsillar area and often without any swelling of the tonsils.

Discussion.

Sir JOHN BROADBENT said that the illustrations depicted very accurately the appearance of the throat in diphtheria, Vincent's angina, and follicular tonsillitis. He agreed that the membrane in diphtheria was ashy grey or whitish in colour and not like wash-leather. There was little difficulty in diagnosis in such definite cases as were portrayed, but there were many others in which the appearance was less characteristic or only suspicious, where bacteriological examination alone could supply the diagnosis. The same was true of cases seen first in a later stage. Some cases of scarlet fever with ulceration of the throat presented great difficulty, for they might be almost exactly like diphtheria, and the two were occasionally combined. In these cases cultivation from the throat was important. Mild cases might go undiagnosed and become carriers if there was no bacteriological diagnosis. He raised some doubts as to the specificity of the influenzal angina, and asked whether influenza had been proved to be the cause.

Dr. F. PARKES WEBER referred to the herpetic condition of the throat, which had been illustrated. Herpes in the mouth, in his opinion, was nearly always bilateral and of the catarrhal form, not herpes zoster. It was rare on the soft palate. He compared it with herpes met with on the nose and face, remote from the lips, in mild pneumonia. He had seen in 1918 a peculiar kind of superficial ulceration of the soft palate, having a greyish appearance and butterfly-like in shape, one patch being on the uvula and a wing on each side of the soft palate, to which the name "pterygoid" had been applied. A similar condition had been seen in newly-born children and had been ascribed to rough swabbing.

Dr. W. HILL said that there were occasional cases in which reliance must be placed on the bacteriological findings. Mistakes were likely to be made in diphtheria when the lesions were multiple while the throat was clearing up. In several instances he had met with combined lesions. It might be impossible to distinguish between Vincent's angina and diphtheria from the naked-eye appearances. The "coccal" patches depicted as influenzal might certainly occur in influenza, but they were an epiphenomenon, and might also occur apart from that disease. In difficult cases the illustrations would not help.

Dr. MONTAGUE SMITH narrated a case of what appeared to be typical follicular tonsillitis from which Klebs-Löffler bacillus had been recovered.

Dr. DRINKWATER, in reply, said that he had not suggested that bacteriological examination was unnecessary; it had been done in every case. If the appearances which he had demonstrated were better known by the general practitioner, who saw the cases in their early stage, there would be far fewer inexcusable mistakes in diagnosis, nor would diagnosis be delayed for the time necessary to receive a report of bacteriological examination.

Some New Methods of Illustration.

Dr. T. B. Hyslop read a paper on Some New Methods of Illustration, with pictures from an epidiascope. After brief reference to wood-cutting, typo-etching, lithography, photographic, and allied processes of illustration, he drew attention to "ortho-printing," a method by which pigments were conveyed direct to natural objects and the printed impressions taken from the objects themselves. Ortho-printing could be used for rapid and correct illustration of natural objects, such as ferns, grasses, leaves, flowers, sea-weeds, feathers, fabrics, cloths, laces, surfaces of metals, &c., in art for designs, wallpaper, stencilling, Gesso, woodwork, wood staining, metal work, pyrography, book covers, objects of art on wood, glass, china, and textile fabrics. The process was so simple and the results were so accurate that it would be of use in schools, colleges, polytechnics, &c., either for students to make their own illustrations or for the preparation of slides for lantern projection. Brief reference was then made to the adaptation of the Sherringham daylight reflector for correcting colour effects in artificial light, and to the further elaboration of ortho-printing for lithographic duplication.

Cardiff Medical Society.—At a meeting of this society held on Jan. 20th Dr. Alfred Howell showed a case for diagnosis. The patient, a married woman aged 45, the mother of four healthy children, had always suffered from epistaxis, severe and frequent in childhood, less so in later years; last attack two months ago. Severe hæmatemesis from gastric ulcer when 13 years of age. For last five years a moderate jaundice, no history of colicky pains or rigors. Had not lost weight and had been able to do her housework throughout. No sign nor history of syphilis. A moderate deafness of many years' standing. Urine contained bile. Fæces light in colour. Liver much enlarged to level of anterior superior spine. The edge, well defined and regular, the surface granular, but no large nodules to be felt. The spleen enlarged to the level of the anterior superior spine. Red blood count 4½ millions. Hæmoglobin 80 per cent.; white corpuscles 5200 in normal proportions. Wassermann reaction positive; other organs normal. The diagnosis lay between visceral syphilis, Hanot's hypertrophic cirrhosis of liver, and splenic anæmia (Banti's disease). In spite of the positive Wassermann reaction, the regularity of edge and surface of the liver, and the absence of history and signs of venereal disease made syphilis improbable in Dr. Howell's opinion. Between the diseases named after Hanot and Banti the difficulty in diagnosis was great, and upon it depended the question of operative interference. The age, the great enlargement of the spleen, the presence of bile in the urine, and the leucopenia were in favour of splenic anæmia.—During the discussion which followed Dr. Lyne Blight took the view that the case was one of visceral syphilis, and Dr. Ivor Davies that it was Hanot's cirrhosis.—Dr. Ivor Davies showed a case of Pseudo-hypertrophic Muscular Paralysis. The patient was a boy of 9, first seen at 5 years of age, when the characteristic physical signs were fully present, and there was a history of the peculiar attitude and gait dating from 2 years of age, when he commenced to walk. Two of the mother's brothers were similarly affected, and died at the age of 13 and 15 years respectively. Dr. Davies referred to five similar cases seen by him with a definite history of the disability dating from infancy, and expressed the opinion that this experience supports the view that the pathological changes are antenatal in incidence, and become apparent clinically at a much earlier age than is commonly supposed.

The jubilee of the Cardiff Medical Society was celebrated on Feb. 11th by a meeting of the society and a dinner in the evening. It is interesting to note that Colonel A. W. Sheen, the President of the society, is the son of Dr. Alfred Sheen, who was the first secretary when the society started in 1870. An interesting address was given by Dr. T. D. Lister, who dealt with Some Aspects of the Tuberculosis Problem. An abstract of this address is given in the present issue of The Lancet. The dinner, like the meeting, was well attended, among the guests being the Lord Mayor of Cardiff, Mr. G. F. Forsdike. In the speeches references were made to the future development of the Welsh National Medical School as an integral part of the University of Wales and of the life of the Principality.

Norwich Medico-Chirurgical Society. — A meeting of this society was held at the Norfolk and Norwich Hospital on Feb. 3rd. A proposal to amalgamate the society with the Norfolk branch of the British Medical Association had been brought up at a previous meeting and since considered by the committee, who now reported that they did not consider the amalgamation advisable at present.—Mr. G. Maxted showed two cases of Primary Optic Atrophy in women. One of these he considered to be due to a tumour of the pituitary body. — In discussing the cases Dr. A. J. Cleveland said that the American surgeon, Cushing, advocated removal of pituitary tumours by operation, which was, in his opinion, quite an easy procedure. —Mr. W. E. Wyllys (Yarmouth) related a case of a Dislocated Cataractous Lens which he had removed by linear extraction.—Dr. H. J. Starling spoke on auricular Fibrillation, and showed three cases illustrative of the condition. He referred to Mackenzie's and Lewis's researches, which had demonstrated the existence of auricular fibrillation as a clinical entity. The cases exhibited showed very well the chief important diagnostic points of auricular fibrillation—viz., a pulse which remained irregular at varying rates, whether fast or slow, and an indistinct muffled diastolic murmur which replaced the typical pre-systolic murmur of mitral stenosis.—Dr. Starling also showed two cases of Subacute Infective Endocarditis.—Dr. E. B. Hinde showed a case of Tuberculous Shoulder and a case of Menierè's Disease.—Mr. C. Noon commented on a case of Actinomycotic Infection.—The following specimens were exhibited:—A Lacerated Kidney and a Ruptured Kidney, both injured whilst playing football. —Mr. E. W. Everett: Uterus and Tubes removed for Gonococcal Infection.—Mr. Noon: Arteries from the Leg of a case of Senile Gangrene.—Mr. A. J. Blaxland: Uterus showing Carcinoma of One Lip of a Hypertrophied Lacerated Cervix; also a Tuberculous Kidney removed by the Abdominal Route.—Sir H. A. Ballance: Radiogram of a Right Kidney with two very large calculi. He also showed a Peptic Ulcer of the Jejunum; and a Duodenal Ulcer, causing fatal hæmorrhage, with a peptic ulcer of the jejunum in addition.

Leeds and West Riding Medico-Chirurgical Society.—A meeting of this society was held on Feb. 6th. The cases and specimens shown were not numerous, but were of interest; whilst some shed light on yet obscure points in pathology.—Dr. C. W. Vining showed temperature charts from a soldier who, in 1916, whilst in Mesopotamia, had suffered from sandfly fever. About two and half years later the patient developed a remittent fever. Careful and repeated physical examination revealed no signs. Blood examinations, cultures from bowel contents, blood, and nasopharynx were equally bare of result. The patient was kept in bed under varied treatment, but with no effect on the temperature, and he lost weight. He was allowed to get up; the temperature immediately began to wane and in a few days became normal. He gained weight. On being put back to bed the temperature again rose, with loss of weight. Alternations of bed and "out of bed" always showed the same phenomena. Finally he was kept up, and now appears to have regained his usual health.—Mr. E. R. Flint showed a case of unusual interest. The patient, a man, had, when 24 hours old, been operated on by Mr. H. Littlewood for imperforate anus. Five months later he developed abdominal distension with marked constipation, which was relieved by drugs and enemata. Ten years later he was troubled with abdominal discomfort and constipation. In May, 1918, there was enormous distension of the belly, again relieved by enemata, but in the August following a Paul's tube had to be tied into the colon. There was never any obstruction, and all the time the anus admitted two fingers. Later the tube came out and the bowel was closed. The condition, however, recurred in November, and on opening the abdomen the sigmoid was found to be enormously distended: this portion of the gut was resected, anastomosis done, and the belly closed. The dilatation was purely local and measured 22 inches in circumference. The man is now well and working. The case was one of Hirschsprung's disease—obviously a congenital abnormality and not dependent on obstruction, and associated only with the imperforate anus.—Mr. H. Collinson, Dr. L. A. Rowden, Mr. J. F. Dobson, Dr. G. W. Watson, Dr. W. MacAdam, and Mr. W. Thompson also showed cases.—Professor T. Wårdrop Griffith gave a paper on the Electrocardiograph and its Teachings. He covered the now familiar ground from Kolliker to Einthoven in an inimitable way. Numerous electrocardiograms, some historic, showed the scientific and practical value of the instrument. Professor Griffith indicated that in disturbances of rhythm the electrocardiograph was a necessity. It was the only method of localising a block in the right or left branches of the bundle of His, or determining right or left ventricular excess. Further, by its use Mackenzie's nodal rhythm had been shown to be auricular fibrillations. The electrocardiograph was the most certain method of diagnosing transposition of the heart.

DERBY MEDICAL SOCIETY.—A meeting of this society was held on Feb. 10th at the New County Offices, St. Mary's Gate. Sir Richard Luce presided.—Dr. S. Barwise, county medical officer, read a paper entitled "The Problem of Tuberculosis," in which he emphasised the view that tuberculous infection enters most frequently by the tonsils or intestines and that the risk from dried sputum is remote.—Dr. W. C. Fowler, medical superintendent of the County Sanatorium, read a paper on Artificial Pneumothorax Treatment, illustrated by some excellent radiographs.—An interesting discussion took place afterwards, in which the President, Dr. C. A. Greaves, Dr. A. E. Brindley, Dr. H. G. Dawson, Dr. Helen Greene, Dr. J. G. Nicholson, Dr. E. Watt, Dr. G. S. Sims, and Dr. H. Barber took part.—After the meeting members inspected the County Laboratories where some interesting slides and specimens were exhibited.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH.—At a meeting of this society, held on Feb. 4th, Dr. Edwin Bramwell read a paper on Encephalitis Lethargica. After briefly outlining the circumstances which led to the condition being recognised as a definite clinical entity, and mentioning the literature of chief importance, Dr. Bramwell described the main features of diagnostic interest. The symptoms vary very much in different types, and also the mode of onset. In many cases the disease sets in gradually, some days or even one or two weeks elapsing before it is fully developed. There was usually a rise of temperature, associated with headache and often vomiting. The patient became increasingly drowsy, and there was frequently diplopia, paresis of accommodation, marked constipation, difficulty in passing urine, and neurotic pains. Extreme asthenia was common, but excitement might also be pronounced. The asthenic type was the most important, but cases might develop suddenly with apoplectiform symptoms; meningitis might also be simulated, or neuralgic pains in the head and limbs be the chief manifestations. The appearance of a typical case was very striking. The patient lay quietly on his back for hours at a time, the face was flushed, the eyes half closed; he was disorientated, appeared to have no interest in anything, and made no complaint. The lips moved, but the face was characteristically immobile and featureless; responses were very slow. There was often marked tremor, fumbling with the bedclothes, jerking movements, delirium, and sleeplessness. The somnolence might deepen into coma. Dysphagia occasionally occurred. A diffuse erythema had been noted. There was general muscular weakness, the third nerve was liable to paralysis, and the facial muscles were often weak from involvement of the seventh. The cerebro-spinal fluid was clear; sugar was present in the urine in two cases observed. The various types of the disease were then outlined in detail and the difficulties of diagnosis discussed. In rarer cases tumour of the brain, paralysis agitans, and disseminated sclerosis might be simulated. The sexes were affected equally, and the disease might occur at any age; it seemed to be commoner in the colder months. The mortality varied considerably in different series of figures. In cases which recovered progress was usually slow, some degree of stupor persisting for weeks or months. There was no specific treatment, but strychnine and quinine both seemed of value in special cases.—Dr. James Miller discussed the morbid anatomy, histology, and bacteriology of the disease, and showed numerous lantern slides and microscopic preparations by way of illustration. The morbid anatomy was not very definite, but there were striking changes in the mesencephalon, including œdema, chromatolysis, and perivascular infiltration. The bacteriology was also discussed, as well as experimental transmission of the disease.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At a meeting of this society, held on Feb. 6th, Mr. A. E. Maylard, the President, in the chair, Dr. W. F. Somerville described "The Bergonie chair, an apparatus for producing a painless, alternating, interrupted electrical current," and demonstrated its application in treatment. By this painless method of faradisation the muscular system was said to be improved and developed, the nutrition of bones and joints improved; the heart's action assisted and breathlessness and œdema relieved; the nervous system quieted and sleep often improved; obesity lessened, constipation relieved, and general nutrition accelerated.—Dr. W. S. Syme, in a communication on "Malignant Disease of the Larynx," pointed out that in this country this disease was much commoner in men than in women, whereas malignant disease of the lower pharynx was commoner in women. Intrinsic disease—i.e., affecting the cords, anterior fornix, subglottis and false cords—might remain as a local condition for a long time, and hence could frequently be treated by thyrotomy and removal of the growth and surrounding tissue. But in extrinsic disease, affecting other portions of the larynx, glandular infection was very common, and the patient was often seen by the surgeon too late for operation. Hence the importance of early diagnosis in cases of persistent hoarseness. Dr. Syme showed a patient whose larynx he had removed two years ago for extrinsic disease. There had been no recurrence and the patient had developed a quite intelligible pharyngeal voice. He reported also three cases of removal of a vocal cord, by thyrotomy, one 2½ years and the other 3½ years ago, without recurrence, and a third more recent case.—Dr. Adam Patrick described a case of Multiple Oriental Sores (Leishmaniasis) infected in Mesopotamia early in 1919 and treated by intravenous injections of antimony. The injections, 11 in all, were given twice weekly, beginning with a dose of 0·04 g. of tartar emetic and increasing to 0·12 g. The seven ulcers present, on hands, legs, &c., had healed satisfactorily. Mr. Archibald Young described, and showed specimen removed by operation from, a case of Ulceration of the Ileum, Cæcum, and Ascending Colon, with Intussusception of the Appendix. The patient, a woman aged 34, had for two years suffered from progressive loss of weight and strength, and from persistent severe pain in the right iliac fossa. The bowels had for long been constipated, but latterly, when moved, they tended to be loose. On examination under an anæsthetic a tumour about the size of a chestnut was made out in the region of the first part of the ascending colon, and suspected to be malignant. Laparotomy was performed, and as extensive glandular enlargement was found, the last four inches of ileum, the cæcum, and ascending colon were excised. The mucous membrane of this portion of bowel showed extensive ulceration, typically tuberculous both to the naked eye and on microscopic examination. Ulceration was specially marked in the cæcum around the partly intussuscepted appendix. Convalescence was uneventful and the patient left hospital a month later greatly improved in health. Mr. Young referred to three other cases of intussusception of the appendix, the first two of which he had reported to the society in 1911: (1) A child, aged 4½, operated on for a suspected partial and recurrent obstruction of the bowel; (2) a woman, aged 24, operated on because of highly acute symptoms suggesting acute appendicitis; (3) a woman, aged 20, operated on in 1917 on account of appendicitis of more chronic type with recurrent attacks extending over several months. The specimen from this case also was shown to the meeting. In all four cases it was probable that the exciting cause of the intussusception of the appendix was the local irritation exciting excessive peristalsis of the organ.

RONTGEN SOCIETY.—A joint meeting of the Institution of Electrical Engineers, the Electro-therapeutic Section of the Royal Society of Medicine, and the Rontgen Society, will be held in the Royal Society of Medicine, 1, Wimpole-street, London, W., on Thursday, Feb. 26th, from 5 to 6.45 P.M., and 8.15 to 10 P.M. A discussion on "Electrical Apparatus in Relation to X Rays," will be opened by Dr. Reginald Morton (Efficiency of High Tension Transformers); Major C. E. S. Phillips (The Problems of Fluctuating and Alternating Currents); and Mr. R. S. Wright, M.I.E.E. (High Tension Transformers). Those wishing to take part in the discussion are invited to apply for advance copies of the papers ten days before the date of the meeting. There will be an exhibition of apparatus in the adjacent rooms. The "Silvanus Thompson Memorial" Lecture will be delivered on March 2nd by Professor W. H. Bragg, C.B.E., F.R.S., on "Analysis by X Rays." Professor Bragg has been Quain Professor of Physics in the University of London since 1915, when he also received the Nobel prize for work on X rays and crystals. Members of scientific societies will be admitted to the lecture on signing the visitors' book. The honorary secretaries of the Rontgen Society are: Dr. Robert Knox, 38, Harley-street, London, W.1., and Dr. R. W. A. Salmond, O.B.E., 51, Welbeck-street, London, W.1., to whom all communications should be addressed.

LIEUT.-COL. G. HORNE, A.M.S., Australia, has been appointed an Esquire of the Order of St. John of Jerusalem in England.

PRINCE OF WALES HOSPITAL, CARDIFF.—Definite steps have now been taken to organise this hospital for civilian service, and a fund sufficient to ensure its future is being accumulated rapidly. The representatives of the army and navy on the council are being replaced by others interested in the industrial life of Wales. The last of the Service patients will be leaving shortly, and the institution will be opened to help maimed civilians. Already statistics have been collected which show that in Wales maimed civilians are equal in number to those crippled in the war. The hospital, which owes its existence to the enthusiasm of Sir J. Lynn-Thomas, was early to originate after-care for surgical cases; its transference to civilian service opens up a vista of surgical possibilities for the future.

Reviews and Notices of Books.

REMINISCENCES OF THREE CAMPAIGNS.

By Sir ALEXANDER OGSTON, K.C.V.O. London: Hodder and Stoughton. 1919. Pp. 335. 16*s*.

THIS book deals with the author's experiences in the Egyptian and South African wars, and on the Serbian and Italian fronts in the recent war; its claim of special interest to medical men rests on the criticisms of the Army Medical Department. Sir Alexander Ogston believes that medical matters will never be placed on a satisfactory footing in the army until the Medical Service is removed from the control of the War Office. This idea is evidently the motive of the book. In Part I. he deals with the Egyptian War and says: "It was not difficult to detect that the best men, physically and otherwise, were in the other branches of the army, while it was the residuum only which were attracted into the ranks of the Army Medical Department." In the interval between the Egyptian War and the South African War the author visited Germany, France, and Russia, and became acquainted with their army medical services, and then concluded that this country was seriously falling behind the other European powers in its medical and surgical provision for war. So that he appears as a frankly prejudiced critic of later events.

Dealing with the South African War in Part II., he says that such impediments as were placed in his way came from the Army Medical Department. He repeats the criticisms of a colonel who commented on the alleged jealousy of the medical department, and on the impediments, described as unreasonable, but placed in the way of the sick and wounded, who thus could not receive the comforts that private benevolence was eager to place at their disposal. This officer also remarked on the scandal, if it occurred, that in bad cases the nursing by trained women was refused by the medical authorities. When Sir Alexander Ogston visited the Third Stationary Hospital there were no antitoxin serums, no X ray apparatus, and the instruments and apparatus were ancient in type. On a visit to the Red Cross depôt in Parliament House at Cape Town he found plenty of useful stores accumulated, but a want of proper organisation for their distribution, so that in his opinion they might almost as well have been left in England, for all the use they were in Africa. He states that the work of the Red Cross was rendered almost of no avail by the unspoken but clearly shown jealousy and even hostility of the Army Medical Department, and that his advocacy of reform in the medical services resulted in the adoption of a hostile attitude towards him by some officers in the medical services.

The author mentions the assertion of Block, the Russian writer on modern warfare, that calamity is likely to ensue if the aid of the civilian population is not early organised and regularly continued on behalf of the sick and wounded in warfare. This aid must supplement the medical organisation within the army, as was fully proved by the South African War, and he considers that there was abundant evidence that the heads of the Army Medical Department in Africa were out of sympathy with progressive ideas and had no proper appreciation of the value of the civilian consultants. He quotes from Mr. Burdett-Coutts's famous description of the terrible conditions following the occupation of Bloemfontein.

Coming to the late Great War, the author's experiences in Serbia have led him to be critical of some of the British contingents. He formed, however, a high opinion of the Serbian hospitals proper and of their medical military officers, and has a warm appreciation of the Italian medical services. The only defect in the Italian hospitals that he mentions is the absence of young and competent women nurses. In all his reminiscences the author indicts the methods of the Royal Army Medical Corps, and while removal of the censorship allows frank criticism, it will also make frank rejoinder possible.

JOHNS HOPKINS HOSPITAL REPORTS.

Vol. XVIII. 1919. Baltimore: The Johns Hopkins Press. With 124 figures. Pp. 452.

THE present volume, which is divided into two parts, contains a number of papers dealing with original contributions from various members of the staff of this famous hospital. In variety of subjects selected and excellence of illustration this report maintains the reputation gained by its predecessors. The ductless glands receive considerable attention, particularly the pancreas, which forms the subject of three separate communications. E. W. Goodpasture and G. Clark demonstrate the presence of a toxic substance in the fresh pancreas which is associated with the B. nucleo-protein. Injection of this protein, or protein combined substance, produces symptoms comparable with those met with in acute hæmorrhagic pancreatitis. An interesting case of diabetes mellitus associated with hyaline degeneration of the islands of Langerhans is described by M. C. Winternitz. The morbid anatomical changes in the pancreas in diabetes mellitus are not always convincing, and consequently such cases as that described are of more than passing interest. In a third paper contributed by A. D. Clark two changes are found to occur in the utilisation of sugar by the living heart tissue, viz.: a condensation of part of the sugar to a non-reducing form and a destruction of the remaining part. The condensed sugar can be again recovered by hydrolysis, but the fate of the destroyed portion was not ascertained.

D. W. Wilson and his collaborators contribute a paper on the question of parathyroid tetany. The tetany which follows removal of the parathyroids can be relieved by acids and also calcium salts. The effects of administration of acids in producing relief from tetany is explained by the occurrence of an "alkalosis" which the body attempts to neutralise by the production of acids in the muscular movements associated with tetany, and a condition of "acidosis" may occur after acute or chronic tetany. Winternitz in a paper on "Some Observations on the Effect of Feeding Glands of Internal Secretion to Chicks," describes the effects of dried anterior lobe of the pituitary body on the growth and development of the reproductive glands in both sexes. In some cases the effects on development and egg-laying capacity were very striking. A number of papers deal with cellular metabolism and histological changes in the cell, and have a bearing on the question of malignant tumours. The relation of old age to cell overgrowth and the occurrence of malignant tumours is described by Goodpasture and G. B. Wislocki. M. T. Burrows and C. A. Neymann have studied the metabolism of cells in vitro and the influence of α-amino acids on embryonic chicken cells. Their observations tend to show that cells are unable to live in any great concentration of amino acids.

A number of papers will interest the clinician, and many of them illustrate the thorough and painstaking way in which the cases have been worked out. Bayne-Jones contributes a paper on Carcinoma of the Pleura with Hypertrophic Osteo-arthropathy, with a description of a case. E. D. Plass, in addition to giving an extensive bibliography, comprising 204 papers dealing with various congenital anomalies of the œsophagus, describes a case of congenital atresia of the œsophagus, with tracheo-œsophageal fistula and fused kidney. A paper on Gaucher's Disease, by J. H. M. Knox and his collaborators is of interest, as the two cases described were infants, whereas the literature on this disease is mainly confined to its occurrence in adults. As illustrating the path of spread of generalised tuberculosis, a paper by Winternitz, in which a case is described of generalised miliary tuberculosis which occurred as the result of extension of a tuberculous pericarditis into the heart cavity.

The number of papers in the present volume exceeds that of previous years and the pathologist, histologist, morbid anatomist, and clinician will each find papers of special interest to him in this collected work. Such reports illustrate the advantages possessed by a hospital and university medical school, not only in the coöperation of their work, but the numbers of workers available to investigate the valuable clinical material.

PHYSIOLOGY AND NATIONAL NEEDS.

A Course of Public Lectures delivered at King's College. Edited by W. D. HALLIBURTON, M.D., LL.D., F.R.C.P., F.R.S., Professor of Physiology, King's College, London. London: Constable and Co., Ltd. 1919. Pp. 162. 8*s*. 6*d*. net.

SOME seventy years ago Sir James Paget dwelt, in a public address, on the importance of the study of physiology as a branch of education for all classes, believing that even a moderate acquaintance with its principles, acquired early in life, would benefit a man both in body and mind. He also pointed out that none of our untaught faculties, neither senses nor instincts, were sufficient guides to good or guards from evil, even in the ordinary conditions of civilised life, and that this was particularly so with regard to health. His statement that while endeavouring to improve present means of life men took no pains to prevent or remedy the future evil cannot be wholly applied to the work which was carried on in our laboratories during the war, but now that the immediate menace is passed it behoves us to see that apathy does not supplant the enthusiasm born of necessity. While it is admitted by thinkers generally, and by the more thoughtful of our legislators, that education of the people is a great national asset, the idea conveyed by the word education does not, save among a very small minority, include those sciences which directly bear upon the health of the people; yet apart from the utility which a broad knowledge of physiology and hygiene, for example, may have on the individual, there is the even greater effect which such a knowledge on the part of the people will have on the nation as a whole.

We are controlled by public opinion, and efforts to apply the discoveries of medical science are wasted unless backed by that opinion. Public knowledge is the remedy, and such lectures as those delivered in the spring of last year under the auspices of the Imperial Studies Committee of the University of London, are good examples. These lectures were briefly reported in THE LANCET at the time they were delivered, and, like the preceding course, "Animal Life and Human Progress,"[1] illustrate the needs and uses of science during the stress of war with its implied application in times of reconstruction and peace. In the introductory lecture, Physiology and the Food Problem, Professor Halliburton, who organised the course, reminds the reader that medical progress during the last four years has probably been more rapid than in the previous 40, and reviews the work done by the Medical Research Committee, the Food Committee of the Royal Society, and by other bodies in standardising and guarding the food supplies of the nation. To this lecture has been added an appendix summarising the main principles of dieting. The two following lectures, by Professor F. Gowland Hopkins and Professor A. Harden respectively, demonstrate the effect of vitamines and the pathological results of their absence in diets; and in the fourth lecture Professor Noël Paton shows the importance which physiology plays in the study of disease, illustrating his theme by showing how this science came to our aid during the war. Emphasising the importance of physiological study, he says: "Without a training in medicine the physiologist can approach the study of disease with some prospect of success; without a knowledge of physiology the physician is merely groping in the dark." Professor A. Dendy gives an interesting account of what was done during the war to prevent the destruction of grain by weevils; and the last lecture, which was delivered by Professor M. S. Pembrey, is a plea for improving the health of the nation by muscular exercises in the form of games, sport, or work in the open air.

---

[1] THE LANCET, June 28th, 1919, p. 1120.

1. DISEASES OF THE SKIN.

By RICHARD L. SUTTON, M.D., Professor of Diseases of the Skin at Kansas School of Medicine. Third edition. London: Henry Kimpton. 1919. With 910 illustrations and 9 coloured plates. Pp. 1084. 42*s*. net.

2. SKIN DISEASES.

By FREDERICK GARDINER, M.D., Lecturer in Skin Diseases at the University of Edinburgh. Edinburgh: E. and S. Livingstone. 1919. With 46 illustrations. Pp. 160. 6*s*.

1. Dr. Sutton has brought the third edition of this handsome volume carefully up to date, as reference to the various maladies discovered or more widely recognised during the war will prove to the modern student. Thus there is a brief but succinct description of the effects upon the skin of tetryl, of mustard gas, and of other chemical irritants which have been widely used in the preparation of munitions or in active warfare. We note also reference to the use of remedies discovered and proven to be of value during the war, such as dichloramine-T, and the paraffin-wax treatment of burns. Curiously, Dr. Sutton does not mention that the employment of this latter agent was first popularised by the results obtained in the treatment of war burns by the "ambrine" of Dr. Barthe de Sandfort in Paris. Full and complete monographs on the less common maladies are not to be found in this volume, but though the descriptions of rare diseases such as erythema figuratum perstans and necrobacillosis, are very brief, they contain the essential and differentiating features. The references to literature throughout will aid the student seeking further knowledge of uncommon conditions in dermatology. As befits these times, when venereal diseases have been proven to be the frequently unsuspected cause of chronic deep-seated maladies, syphilis is treated at considerable length. The paragraphs on treatment throughout the book are, on the whole, of practical value, and in many cases original. On the other hand, certain details are somewhat perfunctory. Complete X ray details are given for the X ray treatment of ringworm, but in many cases the reference to X ray technique is too vague to be of any use. The information regarding the treatment of urticaria and psoriasis by the injection of a foreign protein is well up to date and very clearly described. The illustrations are of uneven value, though some are excellent.

2. Dr. Gardiner's little volume justifies its claim to be the outcome of experience in lecturing, and is a practical introductory handbook for the student or practitioner. As far as possible, the diseases are described in order of occurrence in practice, though this rule is not adhered to when syphilis and tuberculous conditions are described after such rare maladies as dermatitis herpetiformis and pityriasis rubra pilaris. In view of the importance of adequate instruction in the methods of treatment of syphilis it is disappointing to find so brief a description and such lack of detail as to precise dosage and length of time necessary to continue under treatment. The illustrations, as a whole, are not up to the high standard found in modern text-books of dermatology.

SYMPTOMS OF VISCERAL DISEASE.

A Study of the Vegetative Nervous System in its Relationship to Clinical Medicine. By F. M. POTTENGER. London: Henry Kimpton. 1919. Pp. 328. 21*s*.

TAKING as his subject-matter the symptoms of visceral disease, the author has attempted in this monograph to interpret these symptoms in terms of visceral neurology, and thus to bring out more clearly the relationship between physiology and clinical medicine. The bulk of the monograph is devoted to a study of the innervation of the viscera and visceral reflexes, whose range the author considers extremely wide. He believes, for example, that an inflammatory condition of the lung may reflexly set up impulses passing out not only along the efferent fibres of the vagus, but even along the entire cranio-sacral autonomic system, including the pelvic nerve. In the last section of the book the author deals with the purely physiological aspect of the autonomic nervous system. Although it contains some useful information, this monograph lacks the critical and discriminating spirit which is so important for the successful correlation of clinical observation with physiological evidence; and we do not think the book is likely to prove helpful to the practising physician.

Rectoscopie-Sigmoïdoscopie.

Par le Dr. R. Bensaude, Médecin de l'Hôpital Saint-Antoine. Paris: Masson et Cie. 1919. With 15 plates. Pp. 48. 28 fr.

This monograph on the uses of the proctoscope and sigmoidoscope contains an account of the apparatus and the necessary technique, with brief remarks on indications, contra-indications, and the value of the procedure for diagnosis. The book is not overweighted with text, and the remarks in the three pages devoted to the therapeutic applications of the proctoscope are, indeed, too brief to be of much value. More than half the bulk of the book is taken up by 15 pages of excellent illustrations, most of them in colours. The normal appearances are illustrated as well as the pathological, and this "Atlas of Rectoscopy" should be found very useful as a guide for those who are beginning an acquaintanceship with the rectum.

Oto-Rhino-Laryngology.

For the Student and Practitioner. By Dr. Georges Laurens. Authorised English translation of the second revised French edition by H. Clayton Fox, F.R.C.S. Irel. With a Foreword contributed by J. Dundas Grant, M.A., M.D., F.R.C.S. Bristol: John Wright and Sons. 1919. With 592 illustrations. Pp. 339. 17*s.* 6*d.* net.

Clinical teaching in oto-rhino-laryngology in France appears to be in much the same state as in this country, otherwise neither this book nor its translation into English would have been needed. It is an attempt, and should be a very successful one, to interest the practitioner in these subjects, to persuade him not to treat disease of these regions without examining the parts affected, and to show him how to make the necessary examinations. The book is on somewhat original lines; each section on treatment begins with a paragraph on "what to avoid," and is followed by "what to do." Elaborate illustrations are absent, but it abounds in excellent line drawings and diagrams, some of them, as the author says, "almost puerile in their simplicity, which have been inserted in order to visualise and fix the mental picture." The writing is concise and, as perhaps must be in a work of this kind, exceedingly dogmatic. It is also very uneven; thus, while much space is devoted to the detection of deafness simulated by malingerers, a subject usually outside the duty of the general practitioner, no mention whatever is made of the testing of ordinary cases of deafness with the tuning-fork to distinguish middle-ear from labyrinthine deafness, which is much more often required and is quite easy to do. A great deal of attention is given to balneological treatment, which is not greatly in vogue for these diseases in this country. There is a relatively very long description of respiratory and gymnastic exercises.

As would be expected in a book reflecting French practice, general anæsthesia is not advised in a large number of operations in which it is regularly used in England, this being due to the fact that the science and art of anæsthetics is in a less progressive state on the continent than among the English-speaking peoples. Of "tonsillotomy for practitioners," it is said, "never employ the guillotine"; morcellement is the method advised, and Dr. Laurens appears to believe that the entire tonsil is easily removed by this method, and says: "Anæsthesia—in the young child: let him be firmly held by an assistant; in adults and reasonable children above the age of 8 or 10 years, local anæsthesia." It will be seen that the English family doctor will not be wise to follow all the advice given in this book implicitly. Even more open to criticism is the statement on malignant disease of the tonsil that "treatment = 0, especially no surgery." In short, the work being dogmatic, statements can be found which should be qualified and taken as a whole, when the practitioner will find much to stimulate his interest in a group of subjects of great importance in general practice, and the specialist, too, may get help from the pithy descriptions and clever diagrams to enliven his clinical teaching. The translator's work has been well done; it would have been more useful to the average doctor if the prescriptions had been given in imperial as well as metric measures and, especially, if certain drug names, such as guipsine and goudron, unfamiliar here, had been explained.

Diseases of the Throat, Nose, and Ear.

For Practitioners and Students. By W. G. Porter, M.B., B.Sc., F.R.C.S. Edin. Third edition, fully revised under the editorship of A. Logan Turner, M.D. Edin., F.R.C.S. Edin. Bristol: John Wright and Sons. 1919. With a photogravure portrait of Major Porter and 79 illustrations, 44 of which are in colours. Pp. 300. 12*s.* 6*d.*

We welcome the third edition of this excellent little manual. The first edition was produced in 1912, the second edition was brought out by Dr. P. McBride in 1916, during the absence on active service of the author, who was killed in action on June 8th, 1917; and now a third edition has been prepared as a pious contribution to his memory by his old friends and former colleagues in Edinburgh. Dr. Logan Turner has revised the chapters on Diseases of the Larynx and the Nasal Accessory Sinuses, Dr. J. S. Fraser has amplified those on Suppuration of the Labyrinth, Nerve Deafness, Chronic Catarrhal Deafness, and Otosclerosis, while a useful description of vestibular tests has been contributed by Dr. J. Milne Dickie. The alterations are few, and we have here a first-rate text-book of its size and scope, well written, well printed, and well illustrated.

The Microscopic Anatomy of the Teeth.

By J. Howard Mummery, D.Sc. (Penn.), M.R.C.S. London: Oxford University Press. With 243 illustrations. Pp. 382. 25*s.*

During recent years Mr. Howard Mummery has contributed several valuable papers to the Philosophical Transactions of the Royal Society, and no one is better fitted to write a text-book on the subject, for he has taken the trouble to investigate every branch of it, confirming or rejecting statements which have been generally accepted; and while he gives a clear account of his own views, he is chivalrous in describing the views of others.

In the introduction he gives a concise account of the functions of teeth and modern views on heredity. The first chapter deals with the development of the teeth, and contains a lucid description of the theories which have been formulated to account for the evolution of the human molar teeth. The two following chapters are devoted to the enamel, and the structure and development of this tissue in the animal kingdom is graphically described. Attention is directed to the view of Smreker that "the majority of the prisms in human enamel are not rounded or polygonal in transverse section, but have an arched form owing to the prisms being longitudinally grooved and fitted into one another." The author supports this view, and gives several drawings from teased preparations made from the enamel of the elephant, so showing in a conclusive manner that not only do the prisms interlock, but that they are connected by bridges, traversing the interprismatic substance.

The chapter on the dental pulp is very significant, because for the first time in any text-book the distribution of the nerves of the pulp is clearly set out. The medullated nerves which enter the pulp cavity through the apical foramina lose their medullary sheath and neurilemma in time, and give rise to a brush- or fan-shaped expansion of delicate fibres, and form a plexus beneath the odontoblast region. At the lower margin of this layer the delicate nerve fibres of the plexus form synaptic connexions with nerve end-cells which are present in a distinct row among the odontoblast cells. These nerve end-cells are provided with a distal process or axon, which is unbranched and passes direct to the dentine, where it enters the dentinal tube in company with the dentinal fibril. The other processes or "dendrons," given off from the peripheral portion of the nerve end-cells, pass to the odontoblast cells to form a delicate network around them forming synaptic communications with the dendrons of neighbouring nerve end-cells. This mode of distribution of the nerves of the pulp appears to be peculiar to the teeth, as such a mode of termination of sensory fibres in "end-cells" is not met with in other organs.

There are chapters on the dentine cement, Nasmyth's membrane, the periodontal membrane, the attachment of teeth, horny teeth, and the tooth follicle and its connexions. This last chapter contains original observations, for Mr. Mummery has shown that the sheath of Hertwig is not a continuation of the enamel organ, but is a prolongation of other epithelial cells in the follicle which lie to its outer side, these cells moulding and determining the dentine of the root. We congratulate the author on his excellent work.

Practical Biology.

The Cambridge Note Book for Practical Biology (Zoology). Sixth edition. Edited by J. STANLEY GARDINER, M.A., F.R.S, and L. A. BORRODAILE. M.A. London: Henry Frowde and Hodder and Stoughton. 1919. Pp. 76. 5*s.*

ON the principle that a student must make a personal examination of each of the animals he is required to know, this note book is intended to help in the examination of a few type animals, which include the frog, amœba, vorticella, hydra, earthworm, crayfish, cockroach, amphioxus, dogfish, rabbit, and fresh-water mussel. The skull of the dog and the heart of the rabbit are included in the typical subjects. The only illustration is a bold and useful one, showing the general anatomy of the frog. Of histology there is little, and it is very elementary. Brief instructions are given at the top of each page (quarto) and the remainder is left blank for the corresponding drawing by the student. No doubt it has proved useful to the Cambridge student, as is shown by the fact that this is the sixth edition.

The Margaret Book.

By ALFRED CLARK, F.R.C.S., N.Z.M.C. London: John Lane. 1919. Pp. 189. 5*s.*

THE love story of Margaret and Peter, written partly in verse and partly in prose. The story is quite light and serves merely to string together the verses, which are musical and pretty, if they reach no great heights. The introduction of Margaret's illegitimate sister in the last chapter of the book is an inartistic lapse which we fail to appreciate.

A Medley of Verse.

By F. BARBER WELLS, M.B. London: W. H. and L. Collingridge. 1919. Pp. 106. 2*s.* 6*d.*

A COLLECTION of verses, grave and gay, illustrating the author's love of the sea and the countryside. The volume includes a selection of poems from Dr. Barber Wells's "Roll of the Drum," which, now out of print, received a favourable reception on its first appearance, and is still in request.

Wheels, 1919.

Fourth Cycle. Edited by EDITH SITWELL. Oxford: B. H. Blackwell. Pp. 104. 6*s.*

THIS little book needs neither preface nor apology, for its pictorial covers inform us (1) that the authors are among the moderns, and (2) that they rarely hit the bull's-eye. So criticism is disarmed in advance. As a matter of fact, the authors scarcely do themselves justice. They are not so very perverse, and much of their work is quite first-rate and undeniably beautiful. Sherard Vines, especially in The Soldier's Last Love, and Wilfred Owen, whose untimely death we sincerely deplore, have done excellent things. Mr. Aldous Huxley, whose cleverness is beyond doubt, in The Betrothal of Priapus reveals a distressing dyspepsia, which is at least one of the conventional attributes of the poet. In one way or another the remaining contributors have achieved success. Where they fail it is often just from excess of zeal, and our homely advice to them is "Don't press; it's the swing that does it."

We are sorry about the appendix.

JOURNALS.

Parasitology. Edited by GEORGE H. F. NUTTALL, F.R.S. Vol. XII., No. 1. January, 1920. C. F. Clay, Cambridge University Press. 15*s.* net; yearly subscription £2 5*s.*—The opening article on Coloration in Ticks, II., by G. H. F. Nuttall, contains two very beautiful coloured plates representing several species of ticks figured for the first time from the living specimens; these include *Dermacentor venustus*, the carrier of Rocky Mountain fever. It is shown in this article that the colour of ornate ticks may change after a prolonged period of parasitic life.—Professor Nuttall, writing on Regeneration of the Mouth-parts and Legs in Ticks, gives a detailed record of his experiments, and comes to the conclusion that the mouth-parts and legs of immature stages of ticks may regenerate more or less completely when amputated shortly after the ticks have abandoned the host in a fully engorged condition. The power of regeneration in ticks is very important in connexion with their maintenance in nature, where they are frequently injured, and this power is greater in *Ixodidæ* than in *Argas persicus.*—An article by Charles L. Boulenger contains a list of nine species of nematodes living in the donkey and the description of two new species, *Strongylus asini* and *Cylicostomum adersi.*—Philip Manson-Bahr and N. Hamilton Fairley contribute most interesting observations on Bilharziasis among the Egyptian Expeditionary Force, made in 1916–1918, when large numbers of troops were stationed in heavily infected districts. As to the life-history of Schistosomidæ, this paper contains a striking confirmation of the work of Japanese authors, of Leiper and other investigators; it corroborates, also, the results of the recent Bilharziasis Mission in Egypt. There are two forms of bilharziasis in Egypt: (1) the rectal form, produced by *Sch. mansoni*, and (2) the urinary form, produced by *Sch. hæmatobium*. The two parasites differ in life-history and structural development. In *Sch. hæmatobium* the terminal-spined eggs are deposited in excreta (urine and fæces); on reaching the water the ciliate miracidia hatch, and in a period not exceeding 36 hours have to find the intermediary host, a snail of the genus *Bullinus;* the miracidium penetrates into the snail and becomes transformed into an elongated sporocyst, which by budding produces the cercaria. The latter are ejected again in water, where they move actively, and within 24 hours have to penetrate into their final host, usually man, who is invaded either through the skin (during bathing or paddling in the infected water) or through the upper part of the alimentary tract (in drinking the infected water). The parasites finally make their way to the portal veins, where they become adult, male and female. In the case of *Sch. mansoni*, the miracidia hatching from the lateral-spined eggs, penetrate another species of snail of the genus *Planorbis.* The authors produced both forms of bilharziasis in several monkeys via the skin or upper alimentary tract, and noticed a marked pruritus, and, in a few cases, definite skin rashes following the penetration of cercaria. Itching, which did not persist more than 48 hours, or even a rash was observed on boys collecting snails in heavily infected waters. They confirmed experimentally: (1) that *Planorbis* is never infected by the miracidia from terminal-spined eggs (of *Sch. hæmatobium*), nor *Bullinus* with the miracidia from lateral-spined eggs (of *Sch. mansoni*); (2) that cercaria from *Bullinus* transform only into *Sch. hæmatobium*, while those from *Planorbis* only develop in *Sch. mansoni*. Methods of prophylaxis recommended are: (1) destruction of ova in excreta before they reach water; (2) destruction of the intermediary hosts (snails, *Bullinus contortus*, *B. dybowski*, *B. innesi*, and *Planorbis boissyi*); (3) purification of contaminated water-supplies. All these recommendations are very difficult to realise in practice. They strongly advise a microscopical examination of fæces and urine of all persons returning from an infected country (Egypt) to an uninfected one (Australia or India), because the only means of preventing the introduction of this disease into other countries is to confine the carriers of schistosome ova to a limited area, where their excreta would be incapable of reaching any water-supply containing a suitable intermediary host. Finally, the paper contains: (1) a good morphological description of various stages of both parasites, *Sch. hæmatobium* and *Sch. mansoni*; (2) an account of the distribution of molluscan hosts and of their seasonal infectivity; and (3) an investigation of the Sweet-water canal, which was the source of infection amongst Australian and Imperial troops.—An article on Human Intestinal Protozoal and Helminthic Infections observed in Malta, by Thomas Bentham, represents the results of two years' examination of the stools of patients stationed in Malta. 7325 examinations were made of 3370 patients belonging to the four following groups: (1) Troops sent from Salonika Hospital to Malta; (2) garrison troops; (3) troops on their way out from England or France; and (4) prisoners of war. These observations illustrate the endemic nature of amœbiasis in Malta.—D. Keilin writes on a New Saccharomycete *Monosporella unicuspidata* gen.n. nom., n.sp., parasitic in the body cavity of a Dipterous larva (*Dasyhelea obscura*, Winnertz), and gives a description of a new saccharomycete belonging to the genus, the only other species of which was described by Metchnikoff (1884) in connexion with his earlier observations on phagocytosis.—The last paper of this number is on the Occurrence of a Supplementary Chromatic Body in *Maupasella nova* Cépède (Ciliata Astoma), an Intestinal Parasite of an Earthworm (*Allolobophora caliginosa* Savigny), by D. Keilin. The chromatic body referred to is probably derived from the condensation of the extranuclear chromatin.

The British Journal of Children's Diseases. Vol. XVI., October to December, 1919. Edited by J. D. ROLLESTON, M.D.—In an article on Poliomyelitis and Polioencephalitis Dr. Edmund Cautley describes a group of seven cases of affections of the nervous system which were admitted to the Belgrave Hospital for Children within less than a month from different parishes in the neighbourhood. The cases are of interest to the practitioner as regards diagnosis and prognosis, and to the pathologist and epidemiologist as regards the close connexion between poliomyelitis and encephalitis, and the possibility of an endemic outbreak of these diseases. The cases described occurred in children aged from 13 months to 7 years, and were examples of acute poliomyelitis (two cases), polioencephalitis (three cases, one of which was of the lethargic type), encephalitis (one case), and basal meningitis (one case). Dr. Cautley points out that the difficulties in the accurate diagnosis of such cases are very great, even in hospital, where they are generally admitted after some days' illness, and are under careful examination afterwards, while in private practice the difficulties may be insuperable. He regards the reflexes taken in conjunction with the other symptoms as the chief factors of value in differential diagnosis. Examination of the cerebro-spinal fluid may give assistance, but sometimes the fluid cannot be obtained on lumbar puncture, and occasionally the degree of illness hardly warrants the exploration.—Dr. F. Parkes Weber and Mr. T. H. Gunewardene relate the Sequel of the Case of Lipodystrophia Progressiva which they showed at the Section for the Study of Disease in Children of the Royal Society of Medicine on Jan. 24th, 1919, a microscopical report by Dr. H. M. Turnbull being appended. The patient, a girl, aged 13, had died from pyæmia following mastoid disease. The necropsy showed that the body was much wasted. Fat was practically absent on naked-eye examination from the subcutaneous tissue of the upper part of the body. There was no evidence of tuberculosis anywhere. The thyroid gland was rather large, and on naked-eye and microscopic examination was found to be very rich in colloid material. The thymus was represented by a scanty remnant. The brain did not appear in any way diseased, and microscopical examination of one ovary, the pituitary gland, and both suprarenals showed nothing special.—In a paper on School Dental Clinics and their Management, Mr. C. E. Wallis discusses the question of school dental inspection, including the ages at which it should begin, the place where it should be carried out, the proportion of anæsthetic sessions, the choice of the dental surgeon, anæsthetist, and nursing staff, and the appointment of a supervising dentist.—Under the heading of Society Intelligence readers will be glad to see a résumé of the proceedings of the Société de Pédiatrie de Paris, whose meetings have been interrupted for four and a half years. The abstracts from current literature are devoted to diseases of the respiratory system, tuberculosis, and surgery.

Brain. A Journal of Neurology. Vol. XLII., Part 3. London: Macmillan and Co.—This number of *Brain* consists of two papers—one by Dr. Carmalt Jones on War Neurasthenia, Acute and Chronic, and the other by Dr. Kovy of Groningen on Hyperglycæmia in Mental Disorders. The former paper is a personal record of war experiences in the care and treatment of cases of neurasthenia, and the outcome of these experiences is a forcible plea for the intelligent and sympathetic but yet firm treatment of the conditions. War neurasthenia, Dr. Carmalt Jones is inclined to believe, in its various phases—fatigue, loss of control, and visceral disturbance—is to be ascribed to exhaustion of, or intoxication with, the products of the ductless glands, and especially to over-stimulation or exhaustion of the adrenals. The hyperglycæmia and occasional glycosuria in these cases would thus be explained. He has valuable suggestions to offer for the organisation of the methods of treatment. The second paper by Dr. Kovy discusses the significance of sugar in the blood both as a cause of mental disorder and a result. He has made many observations, and concludes that hyperglycæmia may occur with any emotional state in mental disorders, and that emotions, especially of a depressing character, may cause a temporary hyperglycæmia, and even glycosuria, in normal persons. Glycosuria has been also found to occur in animals as a result of fear or anger, and Dr. Kovy concludes that in all the degenerative psychoses in which is found unexplainable variability of mood, the deeper cause may be sought for in the animal world. It will be seen from this brief summary that valuable and suggestive points occur in both these papers, each of which is in some degree complementary to the other.

Discovery. London: John Murray. Price 6*d.*—We announced in our issue of Nov. 1st, 1919, that as a result of a conference called early in that year by the Presidents of the Royal Society, the British Academy, and other important bodies, it was decided to publish, not for profit, a popular monthly journal, in order to keep the public informed of the progress of knowledge in all branches. The first number (January) contains an interesting series of contributions from writers eminent in their subjects. Professor R. S. Conway sends an article (first instalment) on the Secret of Philæ; the Master of Balliol, Mr. A. L. Smith, one on Discovery and Education; and of medical interest is an essay by Professor T. H. Pear on the Modern Study of Dreams. Science in its application to recent warfare is interestingly presented in such articles as Smoke Screens at Sea, by Dr. Slater Price, and Sound-Ranging in War Time, by A. S. Russell. The various contributions are a striking example of the art of writing to the level of the man of general rather than special training or education, while remaining scientifically sound. The writers do not employ the language of their specialism, but that simpler tongue which, to quote the Editor, "we plain men do understand—namely, English." An important feature of the journal is that references to literature on the subjects dealt with are given when possible at the foot of each article, thus enabling a reader, whose interest has been attracted, to pursue the matter further.

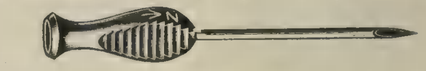
Military Surgeon. December, 1919.—Although the usefulness of physical therapy has long been recognised by the medical profession, the experiences of the war have emphasised its merits from the preventive, curative, and remedial standpoints. Physical education, as preventive physical therapy, demonstrated its value during the war. Surgeon Commander K. Digby Bell, R.N., in an address delivered before the Royal Society of Medicine, and published in THE LANCET of Jan. 31st, urged the country's need of a more comprehensive and a better organised system of physical education, and, moreover, insisted that it was up to the medical profession to see that it got it. But perhaps the fullest account of the results and potentialities of physical therapy is given in a paper on the Importance of Physical Therapy in Military and Civil Practice, read by Commander W. Seaman Bainbridge, Medical Corps, U.S.N.R.F., at the annual meeting of the Association of Military Surgeons of the United States held in St. Louis, Oct. 13th and 14th, and published in the issue of the *Military Surgeon* under notice. Bainbridge goes further and considers physical therapy of importance for physical conditions and disabilities as well as for many functional disorders. He points out that industrial warfare is responsible for a large annual toll of injured persons, and suggests that both civilian and military hospitals in time of peace shall have departments of physical therapy fully equipped, so that they may be utilised, not only for the treatment of the injured, but to secure a maximum of physical efficiency among the general population, and may be made readily adaptable in the event of war. However, it is obvious that the equipment of a hospital for physical therapy is by no means all that is needed for the proper working of a new department. There must be a sufficient supply of skilled exponents of physical therapy, or such treatment will be worse than useless. Captain E. A. Bott, C.A.M.C., of the Military School, Hart House, Toronto, made certain proposals designed to overcome this difficulty in a paper read before the International Conference on the Rehabilitation of the Disabled, held in New York, March 18th–21st, 1919. He drew attention to the fact that if physical therapy was to be conducted with success lay workers must be trained in passive and active movements and in various forms of applied exercises. There is complete agreement among medical men as to the beneficial effects of some forms of physical therapy, and all appear to be of one mind respecting the need for skilled exponents thereof, working under the supervision of specially qualified medical men. The suggestions made by Commander Bainbridge are thus timely and worthy of consideration.

Fifth and Sixth Annual Reports of the Ophthalmic Section, 1917 and 1918. By the Director of Ophthalmic Hospitals. Cairo: Government Press. 1919.—Thirteen permanent ophthalmic hospitals have been built in Egypt since 1906. These are now at work and are aided by four travelling hospitals. There were 81,529 new patients in 1917 and over 1,000,000 attendances, the number being slightly greater in 1918. 13·9 per cent. of all the patients examined were blind in one or both eyes. The cause of blindness in most cases was not trachoma but acute conjunctivitis. Of the operations performed, fully one half were for the relief of trichiasis and entropion. The reports include Dr. MacCallan's tables showing the relation between the incidence of gonococcal and other forms of conjunctivitis and the temperature curve.

New Inventions.

IMPROVED "606" NEEDLE.

THE needle illustrated below is made of nickel, and consequently takes a high polish and keeps a good point. It has a stout bore, which has many advantages in routine work, shortening the time fluids require to pass through it and obviating all chance of clotting of blood during the taking of Wassermann specimens, as blood flows easily through it. The needles are also more easily cleaned inside. The head or "butt" is made of the shape shown in the sketch; on two opposing faces are series of corrugations for improving the grip, and on another face is a small arrow to indicate the plane of the bevel point (the bevel is always kept on this plane when resharpening, so that the needle is always held in the same way when giving injections). These needles are so arranged that the corrugations fall naturally under the first finger of the right hand, while the arrow face of the head, and consequently the bevel point, are directly "upwards," as this seems the best position for insertion into the vein. The rounded butt makes it a very simple matter to slip a small rubber tube over the end for taking Wassermann specimens, difficult when the square-headed needles are used, and necessitating much thicker tubing. The calibre of this butt is standard and fits the Record syringe and Harrison's tap.

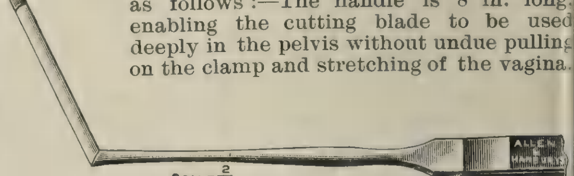


The needle is made for me by the Medical Supply Association, Limited, Holly-street, Sheffield.

Sheffield. E. F. SKINNER, M.A., M.B., M.R.C.P.

THE VAGINOTOME.

ONE of the more difficult steps in Wertheim's radical hysterectomy for carcinoma of the cervix is the final division of the vagina, after the application of the Berkeley-Bonney T-shaped vaginal clamp, preparatory to the removal of the uterus from the body. To overcome the difficulties consequent upon the use of scissors or a scalpel I have devised a vaginotome, here illustrated, the chief features of which are as follows:—The handle is 8 in. long, enabling the cutting blade to be used deeply in the pelvis without undue pulling on the clamp and stretching of the vagina.



SCALE $\frac{2}{3}$

The knife is set at an obtuse angle on the handle, allowing the operator to cut horizontally under the clamp whilst holding the handle vertical, and also slightly tilted. Thus the tendency while cutting across the vagina will be to cut close to the clamp instead of more deeply, to a lower level of the vagina where the bladder may still be adherent. The instrument also carries a blunt bistoury end to safeguard the rectum from being wounded behind. The use of this knife gives a perfectly clean section through the vagina without the ragged appearance that often follows the use of curved scissors or ordinary knife, and renders this step in the operation easy, for it is unnecessary to put heavy traction on the clamp when making the section.

The vaginotome is made for me by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W.

Harley-street, W. ALECK W. BOURNE, M.B., F.R.C.S.

WESTON-SUPER-MARE HOSPITAL.—The wa memorial of Weston-super-Mare is to include a new women' ward, containing 7 beds, with accommodation for nurses The cost of the scheme is £3000.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 21, 1920.

Tuberculosis and Residence.

While our present-day housewife has been charged with a lack of proficiency in housecraft, when compared with her continental sisters, there is no doubt that in this country as in other countries the family is the economic and economical unit of society. To break up the family, and to shelter one member of it in an institution, apart from dire necessity, is to incur an entirely disproportionate expense for an individual, and this can hardly be justified to tax- or rate-payers in the times immediately ahead of us. There are two essential elements in the economical running of a household. One is the mutual adjustment of tastes, celebrated in a familiar nursery rhyme, so that one member takes what the other leaves; the other is a deeply-rooted instinct to keep down expenses within the limits of the family budget. Both of these safeguards are soon lost in any form of institutional life, with far-reaching economical consequences. In view of these considerations, the indefinite extension of sanatorium and training-colony treatment for tuberculosis, however ideally desirable, must be regarded as very difficult at the present time. Fortunately, a larger view of tuberculosis is beginning to prevail, and it is getting to be recognised that institutional treatment has its chief purpose in education, and should be limited to a brief period of tuition in the manner of life suitable to the tuberculous individual.

With one proviso. That the individual, having learned what manner of life he should lead, returns to conditions where he can carry it out. Sufficient food, hygienic environment, and the absence of economic strain, these are the three essential factors which must be on the side of the individual who is putting up a life-long struggle against tuberculosis. And the greatest of these is the last. In the modern factory, as Mr. P. C. Varrier-Jones, among others, has reminded us, if the pace of an operative is slackening, or if he is weak in his attendance, the whole shop is thrown into a state of confusion. The tuberculous worker is either a nuisance to his employer, or risks his health by an attempt to keep up to an impossible standard. But surely it is not beyond the reach of human endeavour to set up special conditions for workers who are incapable of rush against time, and to provide remunerative employment while doing away with the economic struggle—the rock on which so many consumptives are wrecked. Mr. Varrier-Jones has recently idealised a tuberculosis colony as a community of consumptives in which hygienic and economic factors have been adjusted to suit the abnormal physical and mental state of its members. The tuberculous subject must work, and the first practical consideration is to make conditions under which he can work to the full extent of his powers. The recent special report on tuberculosis by Dr. John Robertson, medical officer of health for Birmingham, makes it clear that in Birmingham at least it is not the home environment which is chiefly at fault. The mortality-rate in the decade of highest working efficiency (ages 35 to 45) was 4·5 per 1000 for males and only 1·6 per 1000 for females, and yet, as Dr. Robertson points out, women at these ages spend far more time in the dwelling house than do the men. In his address at Cardiff, reported in our present issue, Dr. T. D. Lister heralds the dawning of the idea that we must try to provide such conditions of life and labour as would render the expensive sanatorium unnecessary. And at the moment the conditions of labour seem most in need of reform, a view that deserves all prominence, for it precludes the relegation of measures for the control of tuberculosis to that day when housing conditions shall be perfect. The intimate association between bad housing and the spread of tuberculosis is too often used as a cover for indefinite delay in preventive measures.

On p. 457 of our present issue Dr. F. Stanley Tinker, tuberculosis officer for North-East Surrey, outlines a scheme for the post-sanatorium employment of the consumptive ex-soldier which meets some of the chief difficulties. The scheme includes both training and permanent employment. So long as they are undergoing training the men would be in receipt of a training allowance from the Ministry of Pensions, and the financial burden of the experiment would be thereby relieved. The municipal workshop, which Dr. Tinker suggests, is to serve the requirements of the discharged ex-Service men in a population of 75,000, and would provide 40 to 50 benches in two workshops, one for training and one for permanent employment. Assessment of hours of work is to be regulated by a medical officer, presumably the local tuberculosis officer, on a strictly individual basis, the man receiving the trade-union rate of wages for each hour of his work, irrespective of the actual amount turned out. The manager in control of the business side of the shops would see to the carrying out of the medical officer's instructions. Dr. Tinker makes large claims for his scheme, the most reasonable of which is that it will not work against any existing proposals, but rather be an adjunct to any of them. The municipal workshop certainly deserves consideration, and especially because it brings the human side of preventive medicine into contact with public affairs. The problem in respect of the tuberculous subject is seen to be the transformation of a weakly member of the community into one who can shoulder his burdens despite his drawbacks.

The Blockade and the Food-supply of Germany.

THE following tabular statement reveals the population of the former German territories in 1911 and 1919:—

Population in Thousands of Persons—1911 and 1919.

Age.	Population.		Increase or decrease.	
	On 1/12/1911 (calculated from Census of 1/12/1910).	On July, 1919 (preliminary estimate of Imp. Statist. Off.).	Absolute.	Per cent. of Col. 1.

Total ...	1000	1000	—	—

The figures are based on the preliminary estimate of the German Imperial Statistical Office, and behind their terrible story lies this message: a five-year age-group of German population drops out, and by so much the German can be regarded as a less menace to the peace of Europe. The figures were communicated on Tuesday last by Professor E. H. STARLING to the Royal Statistical Society, in an address infused throughout with the scientific intention to say nothing save on first-class evidence, and to prophesy nothing that was not supported by that evidence. Taken in connexion with the rest of Professor STARLING'S paper, the figures show alike the preponderating part played by our naval blockade in deciding the final issue, and the influences that remain, to the German detriment, as the result of that blockade.

Commencing with an analysis of the figures showing the total amount of food available for human consumption in Germany during the year 1912–13, the conclusion was reached that before the war the Germans were more richly fed than the inhabitants of either England or France. Nor was the bulk of German imports, as far as they could be classified as food imports, ominously large; it amounted to 8 or 9 per cent. of all foodstuffs. But in those imports was an unduly large proportion of the proteins and fats necessary to make up a normally nutritious diet, and herein lay the cause of Germany's undoing. When the blockade began to take effect, about the autumn of 1916, the calorie value of the foodstuffs at the German disposal became insufficient, nor did they contain a due amount of tissue-building substance. The food directly or indirectly derived from importation accounted for 27 per cent. of the total protein of the diet. To some extent this fact was indicated in an authoritative pamphlet published in Germany at the end of 1914, under the editorship of Dr. PAUL ELTZBACHER, Rector of the Berlin High School. This pamphlet, which was abstracted in English in our columns shortly after its appearance,[1] achieved a wide circulation later in translation by Dr. RUSSELL WELLS, under the title "Germany's Food, Can it Last?" While its information did not fail to impress us with the foresight of the German Government in certain directions, there were many physiologists who were able to see that, if a naval blockade could be maintained, Germany must fall through starvation, though the time that such a wearing-down process would occupy might be vastly protracted by superior organisation, economy, and good weather. That none of these factors came to the assistance of the Germans was shown by Professor STARLING in unmistakable manner. German agriculture, starting from a position which had been given an unduly optimistic appearance by the figures of the German Imperial Statistical Office, and suffering under recurrences of unfavourable weather, by the third year in the war was powerless to meet the demands upon it. Chemical manures were wanting, as were concentrated feeding-stuffs for the cattle; farmyard manures lost their value; the production of meat, fat and milk went down; and, lastly, an unfair distribution of what food there was kept the rich man alive at the expense of the poor.

By the fourth year of the war Germany was a beaten country, despite the power of attack and dourness of defence which, we remember only too well, still resided in the armies. Says Professor Starling: "Three years on a diet insufficient as to quantity and quality, indigestible, tasteless, and monotonous, had a marked influence on the vitality and efficiency of the great bulk of the urban population, which finally resulted in that changed mentality which rendered impossible any further efforts of attack or even resistance." This is not to say that the blockade won the war, for the blockade would have been largely ineffective had not the Allied Armies contained and beaten back the German forces. But the moral is that when at last all the resources of the Allies were found in concentration against the Central Empires, hunger, the cruellest weapon, brought the end. The effects of the blockade remain, and medical readers of the tabular statement which we have quoted will recognise that those effects will be active for many years, as disease takes the toll which follows innutrition.

◆

International Medicine.

The League of Nations Council, which met in London on Saturday last, struck out a bold line in several directions, none of which is likely to have more far-reaching consequences than the appointment of a committee to draw up a scheme for an International Health Commission. How pressing is the need for such a Commission hardly requires emphasis. Many diseases hitherto snugly localised in far-away dominions and dependencies have been mobilised by the war, and are likely to remain mobile in view of the new freedom of communication by land and sea and air. Rabies in England and typhus in Paris have brought this to our knowledge. The task of the international commission which visited and reported on the typhus risk on the Russian frontiers last autumn was rendered largely nugatory by the lack of any central authority to carry out the recommendations. The International Health Commission, when it is set up, should find that its work has been facilitated by the General Council of the League of Red Cross Societies which assembles in Geneva on March 2nd. Pride of place has been there given to the department dealing with medical information and publication. There are other signs which show a tendency towards a pooling of health interests. The National Red Cross Society of Czecho-Slovakia has joined the League of Red Cross Societies. Dr. Octave Monod, of the Pasteur Institute in Paris, has accepted the appointment of assistant chief of the department of tuberculosis under the League, and his experience should be invaluable. Sweden is organising a mobile antityphus hospital of a hundred beds.

We commend this stirring of the waters to Dr. F. F. Simpson, of Pittsburgh, who visited London last week in connexion with a proposal to form a World Congress of Physicians and Surgeons, and who is now in Paris after paying a flying visit to Brussels. At the meeting of representatives of the various specialties in medicine and surgery called last Friday at the Royal Society of Medicine to meet him, Dr. Simpson urged the need, for the benefit of mankind, of forming an international medical council on which every country should be represented. The American view, which he was authorised to set forth, is that each international organisation should forthwith make such adjustments as would permit of a prompt resumption of international activities. He stated that France, Belgium, and Italy had expressed general approval of the scheme, and he proposed that Great Britain and the United States should join these countries in appointing two representatives each on a special investigation committee to meet in Paris next month. The Royal Society of Medicine, while expressing sympathy with Dr. Simpson's objects, felt bound to admit that there were at present a number of specialties without any international organisation, and it was therefore resolved to meet again after obtaining the views of the constituent sections of the society. We can hardly doubt that the verdict will be in favour of using to the full the place of medicine as international reconciler.

Annotations.

"Ne quid nimis."

THE CONSULTATIVE COUNCIL ON GENERAL HEALTH QUESTIONS.

This Council, appointed under the Ministry of Health Act, held its first meeting last week. The Minister of Health, Dr. Addison, who was accompanied by Lord Astor, Parliamentary Secretary to the Ministry, presided, and asked the Council to put before him a statement of the main defects in existing provisions for safeguarding the health of the people, and to suggest remedies from the standpoint of persons who as members of the general public will be affected by the health services supervised by the Ministry. The members of the Council have been appointed with this special purpose in view. Women form a majority of the membership. Lady Rhondda will act as chairman and Mr. Arthur Greenwood as vice-chairman. The other members are as follows: Mrs. Aspinall (United Textile Factory Workers' Association), Councillor C. Aveling (Past-President of the National Chamber of Trade), Mrs. F. Harrison Bell and Miss Margaret McMillan (Labour Party), Mrs. Burke and Mrs. Hood (Women's Coöperative Guild), Mr. George Goodenough (Parliamentary Committee of the Coöperative Congress), Mrs. Ogilvie Gordon, D.Sc. (President of the National Council of Women of Great Britain and Ireland), Mr. W. L. Hichens (Chairman of Messrs. Cammell, Laird and Co., Ltd.), Mr. W. Littler (Civil Service Alliance), Mr. Samuel Lord, F.S.S. (National Association of Local Government Officers), Mrs. Mayo (a member of the Dorsetshire County Council), Mr. F. H. Norman (Professional Workers' Federation), Miss E. M. Phelp (National Association of Domestic Workers), Mrs. Pember Reeves, Lady Edmund Talbot, and Miss Gertrude M. Tuckwell.

A NEW TREATMENT OF COLLES'S FRACTURE.

IT might be thought that the last word had been said on the most common of all fractures, which has been discussed times out of number since it was first described a century ago by Abraham Colles. In the Boston *Medical and Surgical Journal* of Dec. 4th, 1919, Dr. F. J. Cotton, a leading American authority on fractures, gives a new pathology and treatment for this injury. He finds that the bad results often obtained are due to failure to recognise and deal with the backward tilting of the distal fragment. As long as this persists proper reduction of the ulna is impossible, and it is to ulnar luxation rather than to the fracture itself that he ascribes the resulting disability. When the wrist is broken the radius gives way, but the whole damage, according to Dr. Cotton, is best expressed as a rotation backward of the hand about the ulnar head as a fixed point, which tears the ulnar ligaments loose and also breaks the radius. The hand is displaced, with the radial fragment, upwards and backwards, to a varying degree, always with tilting backwards of the lower fragment. After long experience of the accepted manipulations to correct the displacement, it occurred to Dr. Cotton to reverse the mechanism of production. As the ulna is the fixed point about which the hand is displaced, he makes it the fixed point about which he reduces. As the hand is displaced in extension, he reduces it in flexion. As it is displaced in a rotation of supination about the ulnar head, he reduces it in pronation. The older methods of reduction aimed almost entirely at carrying forward of the lower fragment on the upper. For this they are good, and are still used by Dr. Cotton. The new method is, after correcting the obvious displacement of the radius, to carry the hand about the ulnar head as a fixed point into pronation and flexion. This is quite simple. With the hand a little extended, traction and a rocking movement are made so as to free the displaced radial fragment and the dislocated ulna. Then, with the thumb under the ulna, making it a fixed fulcrum, the hand is dragged down into flexion and pronation, traction being maintained at the same time. The finishing movement is a twist of the whole hand about the ulna. The whole may be done as one twisting sweep, rarely needing repetition. For retention the ordinary splints are often inefficient if a first-rate result is desired. Muscle tone holds the fragments against re-displacement in toto, but not against tilting backwards of the lower fragment, especially as there is often much crushed and missing bone at the back edge of the fracture, thus leaving a gap. Tilting can be prevented only by maintaining flexion; this is best done by plaster, preferably applied as strip splints of eight to ten layers of plaster-of-Paris bandage, one on the back from elbow to knuckles, one in front from upper forearm to palm. These are held with a few turns of plaster-of-Paris bandage. The same thing may be done less efficiently with splints provided with an exaggerated pad on the back of the hand and front of the forearm. While the wrist is in flexion the posterior ligaments prevent the radial fragment from tilting backwards, and so long as the ulna is held to the back of the flexed wrist the ligaments can heal to near their normal length. This is important, for their laxity means weakness and often permits subluxation of the ulna with each supination—a common factor in disability. Dr. Cotton finds that this slipping ulna is always undiagnosed. The flexion position need not be maintained more than a fortnight, but if plaster is used it is wise to slit it along one side and keep a careful watch, as the position impedes the circulation. Indeed, the chance of this trouble has prevented Dr. Cotton from publishing the method, long as he has used it. After the flexed position is abandoned, straight splints with the pads described above are used for a third week—never longer except for special reasons. Then a supporting strap of adhesive plaster with a pad in front of the ulna (the ligaments are the last to heal) is worn and changed every three to five days until the hand is strong. Dr. Cotton finds that the hand recovers function more quickly after flexed fixation than after straight splints, though he does not know why.

THE RONTGEN SOCIETY AND RADIOGRAPHIC RESEARCH.

THE exhibition organised by the Röntgen Society, and held at the rooms of the Royal Photographic Society last month (THE LANCET, Jan. 31st), was largely due to the initiative and organising ability of Dr. George Rodman, a past president of the Rontgen Society. At this exhibition an opportunity was given to become acquainted with the enormous strides made during 25 years in every branch of radiographic work. It was, however, an exhibition of finished prints; and only the instructed imagination could picture the corresponding development in the whole technique of radiography, in the intermediate stages, including the introduction of machinery for the production of high-tension current, the improvements in the X ray tube, the skill and ingenuity of the physicist and of the technical expert. We should like to see a further exhibition showing side by side the first apparatus used in radiography in 1896 and an up-to-date model of the present day. The Rontgen Society possesses a collection of X ray tubes illustrating all the steps in the development of this all-important factor in radiography, but so far no effort has been made to provide a display of these improvements in apparatus. The past 25 years have been productive, and it is plausible to suggest that the greatest discoveries have already been made, and that future work will be rather in the nature of improvements in existing apparatus and methods. But since the discovery of X rays paved the way for the no less important discovery of radio-activity, other discoveries may revolutionise our present methods. The tendency of the time is to produce more energy by increasing the size and output of the generating apparatus, and the discovery of a simpler method of producing X rays might do away with the bulky apparatus at present in use. Coördination and research are still needed in all branches of radiography. The application of X rays to industrial problems is likely to become general. The exhibition at the Royal Photographic Society will have served useful purpose if it directs the attention of the public to the need for further investigation and for the whole-hearted support of the efforts of medical men and scientists in this direction. An appeal will shortly be issued for funds to establish a memorial to the late Sir James McKenzie Davidson, and a suitable form for this to take would be the foundation of a Radiological Institute for teaching and research. Attached to the institute should be a historical museum containing collections of apparatus, tubes, and prints, demonstrating the early work and subsequent advances, and the contents of the museum should be constantly kept up to date. Such an institute would become a centre for the coördination of the developments in all branches of radiography—medical, industrial, and scientific.

BLOOD-PRESSURE OBSERVATIONS IN SURGICAL OPERATIONS.

THE first Bulletin of a National Anæsthesia Research Society in U.S.A. deals with the importance of blood pressure observations before and during surgical operation. The systolic and diastolic pressures are taken by the auditory method, using the armlet and snugly binding the stethoscope below it with elastic webbing. Readings can then be taken without disturbing sterile sheets or the continuity of anæsthesia. If the diastolic pressure is between 25 and 75 per cent. of the systolic a case is probably operable, if outside these limits probably inoperable. During operation a 10 to 15 per cent. increase in pulse-rate without change of pressure, or 10 to 15 per cent. decrease in blood pressure without change in pulse-rate, is safe. A 15 to 25 per cent. increase in pulse-rate, with 15 to 25 per cent. decrease in blood pressure, is dangerous. A progressively increasing pulse-rate above 100, with systolic pressure falling to 80 or less, and a pulse pressure (difference between systolic and diastolic pressures) of 20 or less, lasting more than 20 minutes will be fatal. The condition of shock so denoted results in a vicious circle, the low blood pressure and stagnation of blood flow occasioning increasing failure of heart and brain. The anæsthetist must avoid over-dosing the patient in an effort to please the surgeon, who may be demanding a flabby musculature. Relaxation extends to the non-striated muscle, and shock results from hypostatic congestion of blood in the generally relaxed capillaries and veins of the body. Nitrous oxide and oxygen anæsthesia is the best preservative against shock; it does not relax muscle.

BLIND MASSEURS.

THE Association of Certificated Blind Masseurs, registered last July, is now licensed under the Board of Trade. The objects of the Association, over which Sir Arthur Pearson presides, are:—

> To promote the welfare and protect and advance the interests of all certificated and qualified masseurs and masseuses who are too blind to perform work for which eyesight is essential.
>
> To assist and secure the recognition and status of such blind masseurs as aforesaid in and for the purposes of their work.
>
> To provide for such blind masseurs any assistance or advantage calculated to help them to work on terms of equality with sighted masseurs.
>
> To promote coöperation in all matters relating to massage and physical culture between the blind and sighted persons.
>
> To advocate and extend the general use or employment of massage and other physical methods or exercises.

Membership of the Association is conditional on the holding of the certificate of the Incorporated Society of Trained Masseuses—the limitation of title is now too familiar to need comment—or that of the late Dr. Fletcher Little, or such other certificate as may be prescribed by the executive council. The registered office of the Association is at 224–6–8, Great Portland-street, London, W.1.

With the objects of the Association we have the deepest sympathy; and it is eminently satisfactory that care has been taken to provide adequate training for all its members. Far the best way to assist the blind is to render them capable of performing useful and remunerative work, and Sir Arthur Pearson's efforts in this direction have been most successful. There is much to be said for choosing massage as a profession for the blind, though, alas, even here, the blind cannot enjoy all advantages possessed by their unafflicted fellow-workers. Many patients require remedial exercises and re-education as well as massage, and then the blind administrator is handicapped. Unless the limitation is recognised, the blind administrator will be tempted to mete out to patients inferior treatment. Teachers of massage will do well to make this clear to their blind pupils.

SEX DISPROPORTION.

IN one of a series of lectures on Social Unrest, delivered at the Royal Sanitary Institute on Feb. 4th, Dr. R. Murray Leslie marshalled in an arresting manner the facts in regard to sex disproportion and its consequences. He started by suggesting that the numerical preponderance of females over males in England and Wales, amounting to a million and a quarter in 1911, had probably exceeded two millions by the end of the war. The figure is a likely one. Male births, it is true, exceed female births by about 4 per cent., but the mortality among infant boys is so much higher than that among infant girls that even in 1911 the excess of females per 1000 males at all ages was represented by a figure of 68 for England and Wales, while it was 62 for Scotland and only 3 for Ireland. Austria, France, and Germany then occupied an intermediate position with 36, 35, and 26 respectively. From these well-established facts Dr. Leslie went on to deduce social, economic, and national consequences of a momentous nature, associating with the disproportion of the sexes some, at least, of the assumed increase in sexual immorality, the falling off of religious observance, and the decline of the birth-rate in certain elements of the population. He concluded with a classification of women into types, and a suggestion that in racial questions women may become the dominant sex. We agree with Dr. Leslie that his classification may be held by women themselves to be presumptuous, and we distrust the value of the attempts, now so often made, to place men or women into categories in accordance with what are called "types."

COCCIDIOIDAL GRANULOMA.

Coccidioidal granuloma, of which Dr. William B. Bowman,[1] of Los Angeles, recently reported five cases with the X ray findings to the American Roentgen Ray Society, is an acute, subacute, or chronic disease due to infection by a parasitic organism known as the *Oidium coccidioides*. It is sometimes called the Californian disease, as with but three exceptions all the reported cases have lived in or visited that State before contracting the disease, a large percentage of them coming from one district—namely, the San Joaquin Valley. The *Oidium coccidioides*, which is a spherical body varying from 7–30 μ in diameter, consists of an irregular protoplasmic body with a double contoured, highly refractile surrounding membrane or capsule, and multiplies by sporulation. The fungus grows on all types of media. The mode of infection in man is unknown. The naked eye and microscopical pathology, especially in the viscera, is practically identical with that of tuberculosis, and a differential diagnosis can only be made by isolation of the organism. This can easily be done by mixing a drop of pus with a 10 per cent. solution of sodium hydrate on a slide with a cover-slip. Dickson, who collected 40 cases of the disease in 1915, states that a routine examination of cases clinically tuberculous, in which the tubercle bacillus cannot be found, would probably reveal a great many cases of coccidioidal granuloma. The X ray findings in Dr. Bowman's cases closely resembled those of tuberculosis, the peculiar irregular fuzzy appearance of the periosteum being the only distinguishing feature. Treatment was disappointing, no results being obtained by sodium iodide, tartar emetic, copper sulphate, or autogenous vaccines. In the subsequent discussion Dr. M. P. Burnham reported an unusual instance of early diagnosis by aspiration of a joint, followed by immediate amputation of the shoulder. The case was one of the few on record which had not terminated fatally, and suggested that if an early diagnosis was made, and a radical operation performed, a larger percentage of recoveries might be obtained.

---

REFORMS IN FOOD CONTROL.

IN a leading article in our issue of Jan. 31st we outlined the principal features of the last Report (Medical Supplement) of the Local Government Board (1918–19). In Section 17 of that report Dr. A. W. J. MacFadden deals with the work of inspectors of foods, and his observations claim attention, particularly where he suggests reform. He refers at length to the inadequate methods of meat inspection which have long been under consideration, and in regard to which the special experience gained during the war has, in his opinion, greatly strengthened the grounds for instituting changes. Attention, for example, is forcibly directed to the lack of system in the inspection and the facility which is afforded for the unchecked disposal of cow carcasses for human food. It is pointed out that a very considerable proportion of the cows slaughtered annually in this country are seriously affected with tuberculosis, while under conditions which normally exist in England and Wales only a small proportion of these cows ever come under inspection at the time of their slaughter. It must be borne in mind that, whatever inspection may be given to meat after it has been dressed and cut into portions for sale, it is generally quite impossible to detect whether or not the meat was derived from an animal in a diseased condition. Dr. MacFadden strongly advocates the promotion of public abattoirs and the compulsory closing of private slaughter-houses, a policy which has been recommended in these columns on many occasions. In the summer of 1918 considerable anxiety was shown by a number of medical officers of health as to the soundness and wholesomeness of the frozen meat which was being delivered in their districts. Some consignments were rejected by the local authorities and returned to the distributing centre. Public anxiety on the score of health, reports Dr. MacFadden, was largely allayed by the activity shown by medical officers of health and their staffs throughout the country in protecting the country against danger from this source, and much credit is due to them for the success achieved at a time when the borderline between safety and danger was often ill-defined, and when all the circumstances offered temptation to a policy of chance.

Dr. MacFadden reminds us that the vast quantities of foods required by our armies led to organised inquiry into the sanitary condition of food-preparing premises. This involved literally thousands of visits by the Board's inspectors of foods to such premises of all sizes and descriptions in different parts of the country, and careful records have been kept of the conditions found and of the improvements effected. A survey of these records shows that while in a number of the larger factories work has been carried out under conditions likely to ensure the production of sound and wholesome foodstuffs, in many others, even of this class, the opposite has been the case, while in a large proportion of the smaller factories and food-preparing places the conditions disclosed were unsatisfactory in the extreme. The energies of the department have been deeply drawn upon by war requirements, but the circumstances gave our officials a farther reaching searchlight than they possessed before. Food control should benefit by this.

DINNER TO SIR JOHN MACALISTER.

WE may remind our readers that arrangements have been made to hold a complimentary dinner to Sir John MacAlister at the Connaught Rooms on Thursday, March 18th. The dinner is given by the Royal Society of Medicine in recognition not so much of Sir John MacAlister's knighthood as of his 33 years of devoted service to the Society. Members are allowed to bring guests, and applications for the tickets should be made at 1, Wimpole-street, London, W. 1, to Mr. C. H. Fagge or Mr. A. M. H. Gray, who are acting as honorary secretaries of the dinner committee.

THE number of cases of influenza officially announced in Switzerland in 1918 was 664,463, and in 1919 86,058. In January, 1920, in the Canton of Zürich 650 cases of influenza and 24 cases of encephalitis lethargica were medically reported.

A Board of Enquiry has been set up to bring under review cases of long standing still occupying beds in military hospitals, and to report in detail upon their treatment and disposal. The members of the Board are Mr. H. J. Waring, President, Colonel F. MacLennan, R.A.M.C., Dr. W. E. Wynter, Dr. C. M. Hinds Howell, and Mr. T. H. Openshaw, for orthopædic cases when required.

THE LANCET, Jan. 3rd and 10th, 1920.

THE Manager is grateful to readers who have kindly returned to him their copies of THE LANCET of the above dates. He has been pleased to pay the full price for all copies returned, so far as he has been able to establish the identity of the senders, as he is disposing of the copies again to new subscribers.

THE MUNICIPAL WORKSHOP:

A SCHEME FOR THE POST-SANATORIUM EMPLOYMENT OF THE CONSUMPTIVE EX-SOLDIER.

By F. STANLEY TINKER, B.A., M.B., B.C. CAMB., M.R.C.S., L.R.C.P. LOND.,
TUBERCULOSIS OFFICER, NORTH-EAST SURREY.

IN the light of the experience gained during the eight years since the commencement of sanatorium treatment for the working-class population, it has become increasingly evident that the removal of a patient from his home for a limited period of treatment is not sufficient to bring about a permanent arrest of his disease. Attention has therefore been drawn more and more, in the last few years, to the necessity of finding a means whereby the benefit gained by sanatorium treatment may be consolidated, and a useful citizen produced. That the length of sanatorium treatment is unduly short, and can only be expected to produce arrest of the disease in a small percentage of very early cases is universally admitted; but, on the other hand, it must be understood that two great factors operate to make a very prolonged stay practically impossible for the average town-dweller. In the first place he is willing to stay until he feels well, and after that he cannot understand the necessity of continuing treatment; in the second place, the needs of his dependents, who are gradually exhausting his savings, will force him to return to earn for them. The enormous cost would also have to be taken into consideration if any material alteration in this respect were to be made. The problem has therefore become one of improving our methods of after-care, and the following scheme is suggested to fill a gap in the sequence of the methods at present at our command.

Every consumptive may be considered as reduced in physical capacity by 50 per cent. for at least 12 months after his return from a sanatorium. If he is fortunate enough, on his discharge, to secure suitable light work which is well within his physical capacity, he may increase his ability to 75 per cent. of the normal, and even eventually, at that particular trade, to 100 per cent. This applies to a certain number of the best cases only; many have achieved this standard in spite of no provision being made for them. There is, however, a larger percentage for whom there is no such hope: either they must remain idle and starve, or they must do full work with the consequent grave risk of relapse. Even in the case of the discharged soldier, for whom provision in the form of pension has been made, there is the same difficulty, for, although not faced with starvation, idleness, which is only possible to the lowest type, soon becomes unbearable and, in spite of advice, he takes unsuitable work and frequently relapses. That colonies, where the men may eventually migrate with their families, will help a great many of these men to lead useful lives is quite evident, and as a link in the chain they will be an enormous asset, but unless we are prepared to multiply them to an enormous extent they will but touch the fringe of those requiring some such assistance. In this connexion we must not forget the psychology of the average working man whose mentality will hardly rise to the necessity of the migration, and who will always prefer to remain in his urban surroundings. The following outline is for a scheme, suitable for any township, to provide, in conjunction with other after-care, work of a suitable kind in special workshops within easy access of the patients' homes, and under medical supervision.

The Scheme.

The workshops would be divided into two parts. One part to provide training in suitable occupations which could afterwards be carried on in the second part, or permanent workshop. These should be erected on some site, chosen with a view to its accessibility from the urban districts by tram, bus, or rail; both from the point of view of the men employed, and also for the transport of the materials handled in the workshops. In the case both of the training centre and the permanent employment section the conditions and hours of work would be regulated by the medical officer in charge, who would see the men at stated intervals and assess the number of hours work a day.

While the men are under training they would be in receipt of training allowances from the Ministry of Pensions, as in the case of other disablements, but when training is complete they would pass automatically to the permanent section, where they would be in receipt of their assessed pension, according to their disability, but which would remain between 50 per cent. and 100 per cent. of the full pension. Their work would be paid at trade-union rates of wages per hour.

Site of Buildings.

As previously stated, the site should be chosen for its accessibility by tram, bus, or rail. It should not be restricted in size, but should allow room for expansion, with a view to the possibility of including some of the houses of the town building scheme specially allocated for the discharged soldier. With this end in view it would be well to avoid a site surrounded by a populous neighbourhood, or placed in any position where it might acquire the stigma of public curiosity or pity.

The following estimate has been based upon the requirements of the discharged ex-Service men in a population of 70,000 to 80,000.

The following buildings would be required:—

A workshop for training, 20–25 benches.
A workshop for permanent employment, 20–25 benches.
A recreation room and meal room, kitchen, and manager's office.
Instructor's room, implement room, and store room for materials.
Lavatory and washing accommodation.

The buildings, which it would probably be found most economical to obtain of wood, should be lofty, light, and well ventilated by good window space at each side, allowing effective cross-ventilation. They should be heated by a hot-water system and be connected with the electric main. It is not necessary to have an open-sided shed nor to expose the men to extremes of temperature. The ideal would be fresh air and equable temperature.

Work.

This should consist of light manual employment in selected trades, graded from fairly heavy work to the lightest possible for the less able. Two examples which fulfil these requirements would be carpentry and cabinet-making for the more able men, basket-making for the less able men. This side of the scheme is one of infinite difficulty, and upon the correct selection of trades success or failure will rest. Many suitable trades have been cited by the Ministry of Health (in Dr. J. E. Chapman's Memorandum on Colonies), but a great deal will depend upon local demand and facilities, and each particular district should select for its own needs. In this connexion it may be pointed out that the Ministry of Health are arranging for 1000 places for the training of men in existing sanatoriums, and an effort should be made to coördinate the work with them and to concentrate on the same trade, so that the sequence may not be broken, and a definite occupation may be provided for the man on his return home. Outdoor work for a previous town-dweller is not suitable where a living wage is to be earned, nor where large numbers of previous industrial workers are catered for. At the same time, the cultivation of interest in allotment gardening while the patients are under industrial training, would be of great value, as it would tend, at any rate in the summer, to lessen the time spent by the men in their own homes.

Meals and Hours of Work.—Staff.

The foregoing has indicated the necessity of providing meals and recreation during leisure hours. It will be necessary to provide a good mid-day meal, so that no energy is lost by the men having to return some distance home and back. The time gained could profitably be spent in rest. Tea, while not essential, could usefully be added and give a beneficial half hour's rest during the afternoon. The meals should be provided at cost price.

The shops would be open for eight hours a day, and five and a half days a week, but it would depend on the physical fitness of the worker how many hours he would be able to do. The day's work would usefully be divided up as follows: 8.30–12.30, work; interval for lunch and recreation. 2–4, work; interval for tea. 4.30–6.30, work; close.

At first a man will probably only be able to work the morning hours, but eventually many, if not the majority, will increase to the full day. The assessment of hours of work would have to be regulated by the medical officer, who would each week issue a time-table to be followed rigidly. Each hour of work should receive the wage corresponding to the union rate for that trade, irrespective of the actual amount turned out, thus making the scheme fulfil the rôle of the philanthropic employer.

The staff necessary would include the medical officer, who would probably be the tuberculosis officer for the district, and an efficient manager, who would control the business side of the shops, and see that the medical officer's instructions were conscientiously followed. He would be responsible to a committee of management appointed by the local body to whom the scheme was attached, and to whom they would be responsible. It would also be necessary to provide a capable instructor for each trade, both for the training of the men and the control of articles made in the permanent shop. A small staff would also be required to run the canteen and look after the provision of meals.

Home Visits.

We must not, however, rest when we have planned out the day's work of the men. The chief criticism which would come from the promoters of the colony system would be that "any scheme which does not include the whole life of the consumptive must end in failure." Here I am in entire agreement, and I would even go almost so far as to say that our efforts still tend to tackle tuberculosis from the wrong end, and that we should pay far more attention to the present and future homes of the patients rather than attempt to remove them to the distant hills and solitudes of colonies. As part of the scheme I would advocate an active home-visiting schedule controlled from the local dispensary, under which the visitors would endeavour by persuasion, education, and enlightenment, to help the consumptive to cure himself.

Finance.

At the present moment the Ministry of Health do not possess powers to make grants in aid of any but residential institutions for tuberculosis, and pressure will have to be brought to bear on the Treasury to sanction such a grant. This is, however, not an insurmountable obstacle, as already the Ministry are troubled to know what is to become of the men, who are to be trained in sanatoriums, when again turned out into the world, and they will, I think, welcome any proposition which holds out hope of providing this at a reasonable cost. To make any accurate estimate of the total outlay necessary for the buildings and land is, of course, impossible, as this will vary in the different localities. Nor is it possible to give an idea of the value of the labour of tuberculous subjects, which is an interesting question not yet worked out. If properly managed it should cover the cost of wages, and even in time produce a small profit, and in this way reduce the maintenance grant. I estimate that a sum of 30*s.* per head per week would cover cost of upkeep of buildings and plant, power, heating, lighting, water, rates and insurances, resident caretakers, cook, efficient instructors, and some amount of unproductive labour. In some cases, after a period of 12 months to two years, the men will be fit to draft into ordinary industry—that is, after overcoming the period when relapse is most likely. In other cases, of course, the period would be longer, and in some cases permanent. The loss incurred by this latter group would have to be placed against the gain of preventing infection of ordinary industrial workshops and the consequent fresh incidence of tuberculosis on their release from supervision and control.

Summary.

The objects claimed for this scheme are briefly as follows:—

1. Economy in the long run. Less initial outlay. Less frequency, and eventually almost total abolition of relapse, and the production of useful work by an otherwise idle population.
2. Immediate relief. Some such scheme could be put into working order while the plans of colonies are still being prepared.
3. An outlet for the men when their time of training under the Ministry scheme is complete instead of their being faced with the open market of competitive labour in the old unsuitable workshop.
4. It will work in and not against any existing or proposed scheme, and will form a very necessary adjunct to them.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Appearance of Typhus in Paris.

A DOZEN cases of typhus were found in Paris last week, the bacteriological diagnosis having been established at the Pasteur Institute. The patients were isolated immediately, and the Prefect of Police has issued instructions that the search for and investigation of any new cases are to be conducted with special care. Till now there have been no new cases, and it is hoped that the little epidemic will not spread. In 1919 a similar restricted epidemic broke out at Marseilles among German prisoners, but was soon checked. The cases in Paris at present have occurred among Polish workmen brought to Paris by refugees from provinces formerly invaded by the Germans. The situation in these provinces also gives rise to some anxiety, as many Polish workmen in a deplorable sanitary condition are arriving there daily. At Toul they have had to be put into barracks and subjected to vigorous disinfection. In this town, which is the point of arrival of the trains bringing Polish labour, there is an emigration bureau, but unfortunately no sanitary control has yet been organised, and it is to be feared that these workmen, once dispersed in the war area for the reconstruction of the towns, may propagate the epidemic throughout the north and north-east of France. In this connexion M. Gabriel Bertrand, professor at the Sorbonne, and M. Blocq Rousseau, have submitted to the Academy of Science an important communication showing the advantages for the disinfection of clothes infested with typhus-carrying lice and of ships infested with rats harbouring plague-carrying fleas, of employing chloropicrine, which was used during the war in offensive gas attacks. This product, of which there is a large quantity available, would be extremely useful if used, as suggested by Roux, in closed vessels.

The Enlargement of the Paris Hospitals.

There has been an enormous increase in the population of Paris, since many of the refugees from the invaded provinces who lived there during the war prefer to stay in the capital, and others cannot return to their ruined homes. The existing hospitals have thus become quite inadequate for the large number of sick people desiring admission. Lying-in hospitals especially are overcrowded, as was indicated last week, and it has been found necessary to vote grants to provide pregnant women with the means to have their babies at their homes. M. Mesureur, Directeur de l'Assistance Publique at Paris, has furnished to the Municipal Council a report on the enlargement of the hospitals. A sum of 150 million francs is estimated in the report as required for new buildings to be erected in the course of the next ten years. The amount needed for upkeep, now about 2,725,000 francs a year, will be some 10 millions.

Feb. 16th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Dublin and the R.A.M.C. Memorial.

A PUBLIC meeting was held last week in the Royal College of Surgeons in aid of the Royal Army Medical Corps Memorial Fund. The President of the College was in the chair, and among those who spoke were the Lord Chancellor of Ireland, the Primate, the President of the Royal College of Physicians, Major-General Gerrard, A.M.S., and Colonel William Taylor, C.B. It was originally intended that the funds collected should go in part to the erection of a memorial in London, with replicas in Dublin and Edinburgh, and in part to provision for the widows and children of the men of the Corps who had lost their lives in the war. It appears that it has been necessary to abandon the latter purpose, and it is now intended to devote all the funds received to the erection of a memorial or memorials.

The Irish Nursing Council.

The constitution of the first General Nursing Council for Ireland was announced last week in the *Dublin Gazette*. It consists of 15 persons, of whom five are medical men and nine are nurses. The medical members are: Dr. E. Coey Bigger, Colonel Sir Arthur Chance, Colonel W. Taylor, Mr. R. J. Johnstone, and Dr. P. T. O'Sullivan. The representation of the various nursing organisations appears to have been fairly arranged.

Nurses' Salaries.

The Belfast Board of Guardians have decided to increase the salaries of probationer nurses as follows: First year, to £15; second year, to £20; third year, to £25; fourth year, to £30. The average salary paid to nurses in a large number of infirmaries and hospitals in the United Kingdom was £121, while the present salary in the Belfast Workhouse was £59, by far the lowest as compared with any institution in England or Scotland. The average now proposed will amount to £90. By revising the dietary of patients and officials in the workhouse the Belfast guardians are effecting a saving of £3500 per annum. It was stated at the weekly meeting on Feb. 10th that the week before there were 230 scarlet fever patients; 21 had since been admitted, 34 discharged, 1 had died, so that on Feb. 7th there remained 216. Purdysburn scarlet fever wards are also full at present. It was also decided to form a further dispensary subdistrict in Ballymacurett, a crowded working-class district of Belfast.

Feb. 17th.

SAVE THE CHILDREN FUND.

AN appeal has been issued by the Labour Committee of this Fund to labour organisations, calling attention to the urgent need for sending relief to the children in the famine areas of Europe. The labour organisations in neutral countries, such as Sweden and Switzerland, have already done much by feeding and housing children from the famine areas. Although it is assumed this cannot be done here, nevertheless there are many ways in which help can be given. The appeal says:—

> "The position in the coming winter, even in Great Britain, will be difficult, with the high prices of milk and other foods, but whatever difficulties have to be faced here are not to be compared with the suffering which thousands of children are undergoing in the distressed countries. We feel sure that your organisation will most readily help in this matter. If all the members of each labour organisation would give something, however small the sum, the result would be to save not merely the health but actually the lives of great numbers of suffering children. Nor could any act provide a more genuine demonstration of the solidarity of the workers the world over."

It is suggested that the fund raised through this appeal should be permanently maintained, and made applicable to the alleviation of the needs of the children of workers in this as well as in other countries. The appeal is signed amongst others by Mr. W. Adamson, M.P., Mr. J. R. Clynes, M.P., Mr. George Lansbury, Mr. J. H. Thomas, M.P., Mr. Arthur Henderson, M.P., and the secretary, Mrs. Pete Curran, who can be addressed at 28, Tavistock-square, London, W.C. 1

HOUSING NOTES.

The "Daily Mail" Exhibition at Olympia.

THOSE interested in the many amenities of the up-to-date house will do well to set aside a whole day for their visit to Olympia. They should plan their arrival for the early morning and visit the more popular exhibits first; by midday there are queues waiting for admission into some of the houses, and exhibitors are far too busy to give away more than a small proportion of the interesting information at their disposal. Thus the all-electric house, and the sectional wooden house made by the Norwegian House-Building Co. are amongst the exhibits which should be seen before 11 A.M. The Ministry of Health's annexe may be visited at leisure, but an attendant is required to explain the exhibits. Those who examine the truncated model cottages nearly all comment upon the small size of their rooms. This is partly due to an optical delusion, and it is to be regretted that adverse criticism should be passed without any demonstrator being present to correct faulty impressions.

Some of the exhibits are of special medical interest. Such are the child welfare exhibit, managed by the Middlesex Hospital; an electric "solarium," which in spite of its name is admirably appointed as a radiant-heat bath; electric sterilisers, which are efficient if expensive—one manufactured by the General Electric Company is particularly ingenious; and, finally, an improved water-closet seat well designed to prevent the possibility of contamination by those using it. Perhaps Messrs. Beck's electric laundry should be mentioned in this connexion; it is an economical outfit both as regards time and power, and the larger plant has a great advantage in that the clothes can be sterilised at the same time as they are cleaned.

The Ideal House.

Those who are seeking the ideal house find themselves confronted at the outset with a wide range of material from which to select its components. The usual brick has scarcely an advocate, because it does not need one. Some very tempting houses are built entirely from wood. One wooden cottage in particular attracted widespread admiration. It was built of unseasoned English elm and had been approved by the Ministry of Health, who, despite its thatched roof, give it the full status of a permanent building and a subsidy allowance of £150. This enables the house—three bedrooms, two living-rooms, kitchen, scullery, and stove—to be built for £300. The remarkable cheapness is due mainly to a saving in the raw material, which is bought at something under 3*d*. per cubic foot. The house can be ready for occupation within eight weeks of cutting down the trees needed for its construction. It might be feared that if this type of construction became popular the stock of elm in this country would be rapidly used up, but no one who knows anything about agricultural labour would share this apprehension. Concrete blocks offer a formidable rivalry to wood, and there are many machines exhibited which manufacture the blocks by unskilled labour "while you wait." The most successful, in our opinion, are those which are made on the principle of the skeletal system—hollow blocks, rigid yet light, with the advantage of the adiathermanous air-spaces.

Heating and lighting form a special section of the exhibition, coal-gas and electricity being the foremost competitors. The cleanliness and convenience of electric heating are apparent to all, but a few calculations make it evident that, even with electricity at 2*d*. or 1½*d*. a unit, economy is still on the side of coal-gas. An interesting plant for heating and lighting from No. 1 petrol spirit should not be overlooked. Although the report of the Coal Smoke Abatement Society published in THE LANCET on Nov. 17th, 1906, is quoted by one gas company in a well-informed pamphlet on the hygiene of gas fires, there was nothing in the exhibits suggesting that the comfortable, extravagant coal fire has been largely superseded.

"Labour-saving" has now become a catch phrase, and many old and well-advertised appliances appear under its guise. The most interesting are usually dependent on electric power, and will acquire considerable significance if the Government's plan for supplying electricity on a large scale should come to fruition. Various plants for the generation of electricity are to be seen, but all are too expensive to be of service to those who cannot afford to pay for labour. Garden and poultry exhibits are in profusion and of high quality. The exhibit of the Board of Agriculture deserves special mention. A model allotment shows vegetables in hearty growth, while at a stall instruction is given in bottling fruits, specimens being shown just as they were prepared in a London cottage to show the different utensils needed.

The World Shortage of Houses.

La Rochefoucauld declares that there is often something not displeasing to us in the adversity of our best friends. His remark might well be illustrated by an article appearing in the number of the official journal *Housing* published on Jan. 5th, and containing a summary of the housing conditions in a number of civilised countries throughout the world. The article in question deals in succession with Canada, where in spite of a Government loan of £5.000.000, the progress of housing has not been rapid; Australia, where the larger cities are suffering from a very pronounced shortage of houses, due in part to the steady flow of the population from country to town; New Zealand where a Parliamentary Committee has recommended the formation of a National Housing Department, and the allocation of £2,000,000 to a housing scheme for families with, in general terms, an income less than £300, plus £25 allowance per child where there are more than three children. South Africa, India, the United States, and France are in the same plight. In Italy, new housing at the cost of £10,000,000 is anticipated, and the Ministry of Industry is making an annual State grant of £400,000, which may be increased if the inhabitants and the coöperative societies show the requisite activity. Germany has perhaps the most acute problem of all, and has been forced in some towns to adopt rationing of house room and the billeting of civilians in private houses. Norway, Sweden, Holland, and Switzerland have all to face housing problems in acute form.

A Stitch in Time.

In addition to the world shortage consequent upon pre-war neglect, as well as upon the loss of labour during the five years of war, we are, in this country, faced with a fresh difficulty. While valiant efforts are being made to raise new houses throughout the land, practically nothing is being done to remedy the wear-and-tear of the large and constantly growing number of working-class houses that are tottering on the brink of the chasm between the dilapidated house which can, and the corresponding house which cannot, be made fit for human habitation. The unfit houses are continuing to be unfit, are becoming rapidly more unfit, and unless quickly patched or reconstructed will deteriorate beyond repair. If local authorities allow that to happen, much of their present effort at rehousing will be wasted, and they will be back in the old game of trying to catch up with the creation of the slum and of never quite succeeding before the next patch of slum has grown.

Measles Spread by Overcrowding.

The ill-effects of overcrowding are always accentuated by the advent of any infectious disease. This was very markedly the case at Barnsley in the spring of 1918, when the town was visited by an epidemic of measles. The medical officer of health, Dr. F. A. Sharpe, has written a special report dealing with this epidemic, in which he attributes a very important rôle to the bad housing conditions. For want of adequate accommodation the young patients had usually to be nursed in the room which served as living room for the rest of the family and as reception room for the neighbours. Besides spreading the disease abroad, this kind of sick room cannot be ideal from the patient's point of view. No less than 232 deaths were recorded during the year from measles and its complications.

The Services.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. H. M. Nicholls retires on retired pay.

Temp. Lieut.-Col. J. F. Haswell (Col., T.F.) relinquishes his temporary rank on ceasing to be employed in the Army Medical Service.

Major R. G. H. Tate to be temporary Lieutenant-Colonel whilst specially employed.

The undermentioned relinquish the acting rank of Lieutenant-Colonel: Major and Bt. Lieut.-Col. G. W. G. Hughes; Majors R. C. Wilson, H. W. Farebrother, G. A. K. H. Reed; Capt. J. R. Hill.

Temp. Capt. W. N. Parker relinquishes the acting rank of Lieutenant-Colonel and reverts to the acting rank of Major.

Major W. Tibbits is placed on retired pay.

The undermentioned relinquish the acting rank of Major: Capts. W. E. Adam, J. C. Sproule, A. L. Stevenson, W. H. S. Burney; Temp. Capt. and Bt. Major R. Bruce-Low; Temp. Capts. A. W. Comber, J. R. Pate, R. Heaton, G. T. Foster-Smith, E. B. Barton, F. R. Barwell, A. G. Anderson.

To be temporary Captains: H. R. McNair, late Can. A.M.C., H. H. Perry, late Can. A.M.C.; Temp. Lieut. P. Carroll.

Officers relinquishing their commissions:—Temporary Majors retaining the rank of Major: R. H. J. Swan, S. M. Cox, R. L. Davies. Temp. Capt. (acting Major) W. N. Parker and Temp. Capt. G. L. Leggat are granted the rank of Lieutenant-Colonel. Temporary Captains granted the rank of Major: H. H. Sampson, W. V. Robinson, J. Porter, C. D. Coyle, E. F. C. Dowding, W. H. Clements, J. Rodger, A. L. Lockwood. Temporary Captains retaining the rank of Captain: G. D. Fairley, T. M. J. Stewart, B. V. Ward, J. R. K. Thomson, A. R. Hargreaves, C. K. Sylvester, E. A. A. Saunders, J. W. E. Cole, N. I. Sinclair, E. K. Gawn, N. B. Capon, R. C. Cooke, P. C. West, S. Forrest, N. F. Graham, H. M. MacKenzie, A. J. McCreadie, I. Feldman, F. C. Robbs, N. J. Judah, R. T. Todd, W. H. Ogilvie, E. E. Lightwood, P. Carroll, W. H. Sheffield, J. F. Allen, J. Caton-Shelmerdine, E. R. Griffiths, A. G. Price, W. E. Fetherstonhaugh, T. L. Clark, H. S. De Boer, G. W. Smith, C. E. Waldron, O. F. D. Airth, C. W. S. Davies-Jones, J. C. Waitham, J. McI. Falkiner.

SPECIAL RESERVE OF OFFICERS.

W. McK. H. McCullagh relinquishes the acting rank of Lieutenant-Colonel.

Captains relinquishing the acting rank of Major: J. Kennedy, G. T. Mullally, T. McEwen, H. W. Maltby.

Capt. B. W. Jones relinquishes his commission and retains the rank of Captain.

TERRITORIAL FORCE.

1st Southern General Hospital: Major (acting Lieut.-Col.) W. Kirkpatrick relinquishes the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

TERRITORIAL FORCE RESERVE.

Capt. W. Hunter, from 4th London General Hospital, to be Colonel.

ROYAL AIR FORCE.

Medical Branch.—Flying Officers to be Flight Lieutenants: T. Montgomery, C. F. Eminson, R. D. Jones. The undermentioned are transferred to the unemployed list: Capts. S. J. Moore, D. Guthrie; Lieut. J. Stark.

Dental Branch.—N. H. Medhurst is granted a temporary commission as Lieutenant. Lieut. P. E. Bernard relinquishes his commission, and is permitted to retain his rank.

INDIA AND THE INDIAN MEDICAL SERVICE.

Col. J. K. Close to be Inspector-General of Civil Hospitals, United Provinces, vice Lieut.-Col. W. H. E. Woodwright resigned. The Governor in Council has nominated Col. J. B. Smith as official additional Member of the Legislative Council of Bombay Presidency, vice Major-Gen. W. E. Jennings resigned. Lieut.-Col. R. G. Turner, civil surgeon, has been transferred from Mussoorie to Allahabad. Lieut.-Col. G. Hutchison, civil surgeon, has been transferred from Allahabad to Gorakhpur. Major Harper Nelson has been appointed Professor of Materia Medica at the Lahore Medical College. Air Lieut.-Col. J. Swann reverts to civil employ in the Punjab. Capt. R B. Lloyd has been appointed to the Civil Medical Department of Bengal. Capt. J. H. Smith, Capt. J. W. Lane, and Capt. C. S. Smith are promoted to Acting Lieutenant-Colonels. Brevet-Major W. McNaughtan, R.A.M.C., military medical officer, has been appointed to hold civil medical charge of Rooker, in addition to his duties, vice Capt. R. V. Clarke, R.A.M.C. The services of Capt. D. O'Malley, R.A.M.C., have been placed at the disposal of the Government of India. Major

A. H. Hayes, R.A.M.C., has been appointed to hold Civil Medical Charge of Naini Tal, in addition to his own duties, vice Lieut.-Col. T. Humber, civil surgeon, granted leave. Dr. R. G. Griffin, Deputy Sanitary Commissioner for Anti-Hookworm Campaign, has been appointed Civil Surgeon, Jalpalguri, in addition to his own duties, vice Major R. E. Lloyd, granted leave for one year. Lieut.-Col. E. V. Hugo has been appointed Professor of Surgery, King Edward Medical College, Lahore. Major C. A. Gourlay, D.S.O., civil surgeon, has been posted to Mymen Singh. Col. J. K. Close to be a Member of the United Provinces Legislative Council, vice Col. C. Mactaggart, C.S.I., C.I.E., resigned. Major R. H. Bott has been appointed Professor of Operative Surgery, Lahore Medical College; Mr. R. L. Stevenson reverts to Bengal.

THE HONOURS LIST.

Capt. H. M. Collins, I.M.S., and Major (acting Lieut.-Col.) A. Spitteler, I.M.S., have been appointed Officers of the Order of the British Empire for valuable services rendered in connexion with military operations in Southern and Central Kurdistan.

BROUGHT TO NOTICE.

The names of the following medical officers are brought to notice for valuable services rendered during the military operations in Central and Southern Kurdistan:—

Lt. (acting Capt.) L. G. Blackmore, R.A.M.C.; Capt. H. M. Collins, I.M.S.; Maj. J. F. Grant, R.A.M.C. Lt.-Col. (temp. Col.) J. A. Hamilton, C.M.G., I.M.S.; Temp. Capt. W. G. Miller, I.M.S.; Capt. (acting Maj.) M. Purvis, I.M.S.; Maj. (acting Lt.-Col.) A. Spitteler, I.M.S.; Capt. (acting Maj.) C. J. Stocker, M.C., I.M.S.; Capt. (acting Maj.) J. M. Weddell, R.A.M.C.

URBAN VITAL STATISTICS.

VITAL STATISTICS OF LONDON DURING JANUARY, 1920.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 9·2 per 1000 of the population, estimated at 4,026,901 persons; in the three preceding months the rates had been 10·1, 11·1, and 10·7 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in Kensington, Hammersmith, the City of Westminster, St. Marylebone, and Woolwich; and the highest in Fulham, Finsbury, Bethnal Green, Deptford, Greenwich, and Lewisham. The prevalence of scarlet fever showed a considerable decrease—27 per cent.—from that recorded in the preceding month; this disease was proportionally most prevalent in Finsbury, Deptford, Greenwich, and Lewisham. The Metropolitan Asylums Hospitals contained 2476 scarlet fever patients at the end of the month, against 2293, 2848, and 2841 at the end of the three preceding months; the weekly admissions averaged 280, against 340, 427, and 350 in the three preceding months. Diphtheria was slightly more prevalent than in December, and has shown a progressive increase since August, 1919: the greatest proportional prevalence of this disease was recorded last month in Fulham, Holborn, Bethnal Green, Wandsworth, and Lewisham. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1001, 1168, 1405, 1572, and 1845 in the five preceding months, further rose to 1971 at the end of January; the weekly admissions averaged 263, against 125, 180, 207, 215, and 239 in the five preceding months. The prevalence of enteric fever was about double that in the preceding month; of the 42 cases notified last month 4 belonged to Fulham, 3 to the City of Westminster, 3 to Hackney, and 3 to the Port of London. There were 25 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 47, 44, and 25 at the end of the three preceding months; the weekly admissions averaged 4, against 6, 5, and 2 in the three preceding months. Erysipelas was proportionally most prevalent in Chelsea, Finsbury, Bethnal Green, Southwark, Battersea, and Deptford. The 49 cases of puerperal fever included 6 in Islington, 5 in St. Pancras, 5 in Bermondsey, 4 in Lambeth, 3 in Bethnal Green, 3 in Wandsworth, and 3 in Camberwell. The 17 cases of cerebro-spinal meningitis included 3 in Bermondsey, 2 in Hammersmith, 2 in Islington, and 2 in Poplar; while the 2 cases of poliomyelitis belonged respectively to Stepney and Lambeth.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the

* Including membranous croup.

deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended Jan. 31st the deaths of 4894 London residents were registered, equal to an annual rate of 15·8 per 1000; in the three preceding months the rates had been 14·1, 14·6, and 14·1 per 1000. The death-rates ranged last month from 11·1 in Holborn, 11·9 in Hampstead, 12·1 in the City of London, 12·1 in Wandsworth, 12·6 in Paddington, and 13·1 in Fulham, to 18·0 in Islington, 18·0 in Deptford, 19·0 in St. Marylebone, 20·5 in Poplar, 21·9 in Finsbury, and 23·0 in Shoreditch. The 4894 deaths from all causes included 361 which were referred to the principal infectious diseases; of these 72 resulted from measles, 19 from scarlet fever, 120 from diphtheria, 78 from whooping-cough, 5 from enteric fever, and 67 from diarrhœa and enteritis among children under 2 years of age. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Paddington, Chelsea, the City of Westminster, Hampstead, St. Pancras, and Wandsworth, and the highest in Stoke Newington, Shoreditch, Bethnal Green, Poplar, Bermondsey, and Lambeth. The 72 deaths from measles were 39 fewer than the average number in the corresponding period of the five preceding years; this disease was proportionally most fatal last month in Shoreditch, Bethnal Green, Lambeth, Deptford, and Greenwich. The 19 fatal cases of scarlet fever were 6 in excess of the average, and included 3 in St. Marylebone, [illegible] in Fulham, and 2 in Islington. The 120 deaths from diphtheria exceeded the average by 59; the greatest proportional mortality from this disease occurred in Fulham, Hackney, the City of London, Shoreditch, Battersea, and Lewisham. The 78 fatal cases of whooping-cough were 9 in excess of the average; this disease was proportionally most fatal in Islington, Hackney, Bethnal Green, Stepney, Bermondsey, and Deptford. Five deaths from enteric fever were registered during the month, against an average of 7. The 67 fatal cases of infantile diarrhœa were 6 below the average; the greatest proportional mortality from this disease occurred in Paddington, St. Marylebone, Stoke Newington, Shoreditch, Bethnal Green, and Poplar. In conclusion, it may be stated that the aggregate mortality in London during January from these principal infectious diseases was 8 per cent. above the average.

(Week ended Feb. 14th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had been 15·3, 15·9, and 15·9 in the three preceding weeks, rose to 17·4 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the annual rate was 18·4, or 1·2 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 8·6 in Barrow-in-Furness, 8·9 in Ealing, and 9·3 in Eastbourne, to 24·2 in Bootle, 27·7 in Liverpool, and 27·9 in Dewsbury. The principal epidemic diseases caused 453 deaths, which corresponded to an annual rate of 1·4 per 1000, and comprised 146 from measles, 120 from whooping-cough, 107 from diphtheria, 56 from infantile diarrhœa, 19 from scarlet fever, and 5 from enteric fever. Measles caused a death-rate of 1·7 in Stoke-on-Trent, 2·1 in Liverpool, 2·4 in Nottingham, 2·8 in Hull, and 3·0 Dewsbury; whooping-cough of 3·6 in Lincoln; scarlet fever of 2·6 in Darlington; and diphtheria of 1·6 in Bolton and 1·8 in Enfield. The deaths from influenza, which had been 85, 66, and 98 in the three preceding weeks, rose to 109, and included 25 in London, 15 in Liverpool, 9 in Birmingham, 7 in Leeds, and 4 in Wallasey. There were 2459 cases of scarlet fever and 2010 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2487 and 2014 respectively at the end of the previous week: 4 cases of small-pox (2 from East Ham, 1 from West Ham, and 1 from Poplar), of which 1 proved fatal, were also admitted during the week. The causes of 47 deaths in the 96 towns were uncertified, of which 13 were registered in Birmingham and 4 in Liverpool.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at 2,400,000 persons, the annual rate of mortality, which had been 15·3, 15·9, and 14·7 in the three preceding weeks, was again 14·7 per 1000. The 326 deaths in Glasgow corresponded to an annual rate of 15·3 per 1000, and included 7 from measles, 4 from diphtheria, 2 from infantile diarrhœa, and 1 from whooping-cough. The 83 deaths in Edinburgh were equal to a rate of 12·7 per 1000, and included [illegible] from measles, and 1 each from whooping-cough, diphtheria, and infantile diarrhœa.

Irish Towns.—The 139 deaths in Dublin corresponded to an annual rate of 17·5, or 1·7 per 1000 below that recorded in the previous week, and included 3 from whooping-cough, and 2 each from diphtheria and infantile diarrhœa. The 159 deaths in Belfast were equal to a rate of 20·1 per 1000, and included 11 from measles, 2 each from scarlet fever and infantile diarrhœa, and 1 from whooping-cough.

NEW CLASSIFICATION OF TRYPANOSOMES: A QUESTION OF NOMENCLATURE.

To the Editor of THE LANCET.

SIR,—Having occasion recently to compare the latest edition of Castellani and Chalmers's "Manual of Tropical Medicine" with my own copy of this most useful work, which accompanied me everywhere while I was on service in the East, I was surprised to find myself confronted, in the section dealing with the trypanosomes, with a number of new, "personal," generic names, amongst which the parasites belonging to the well-known genus *Trypanosoma* had been distributed. On investigating further, I ascertained that these new names were all the result of an effort by Chalmers to classify the trypanosomes.[1] In an almost apologetic conclusion to this paper—as if the author felt some attempt to justify himself were necessary—Chalmers adds: "It may be said that the time is not ripe for an attempt to classify the trypanosomes, but someone must make a beginning, and without doubt Professor Minchin would have formulated a classification had he lived."

It may be readily agreed that an endeavour to separate and define the chief types in the case of a large number of different forms, such as are at present collected together in the genus *Trypanosoma*—so far as this can be done upon the available data—is likely to prove of assistance to workers on the group. Even though such a classification can be yet only tentative, it may help to clarify or crystallize, as it were, one's own ideas upon the subject. And it was, I know, Professor Minchin's expressed hope to write next a book dealing specially with the trypanosomes. It is not my intention, however, to discuss here the merits of the proposed classification.

Personally, I should have read Chalmers's paper with much more interest and profit if the arbitrary and at times absurd nomenclature suggested had not produced a feeling of half-amused irritation. And the purpose of this note is to say that I think the time has come to protest strongly against the ever-increasing use of the names of persons for new genera by those working on the protozoa. As the recorder of protozoa for the *Zoological Record* since 1901, I have noticed a marked tendency in this direction, unfortunately, during recent years, but I consider the limit has been overstepped in the paper by Chalmers. This much I can certainly say, as an associate and co-worker with my late professor for a period of many years, that in any regrouping and subdivision which it had seemed good to him to propose he would have had due regard to the established rules and usages of zoological nomenclature; these would not have been violated in the manner which is only too apparent in the case of Chalmers's new names. As for such a verbal atrocity as "*Trypocastellanellaneæ*"—it could not have been perpetrated by Professor Minchin. I well remember how vastly amused he was over the analogous word "*Spiroschaudinnia*" when that was created.

If the scientific name for an animal affords an indication of the character or affinity of its bearer, or of some biological feature associated with it, this name is of definite and practical use. But any usefulness in this respect is largely stultified by the adoption of a personal name for that of the genus. No information of scientific value is afforded thereby; no clue to the nature or relationships of the type thus named. Take the case of the piroplasms and related forms, for example. Of what use are the names given to *Theileria*, *Nicollia*, *Nuttallia*, *Smithia*, *Toddia*, and so on? I know that these parasites have some connexion with piroplasms, because they are named after well-known contemporary workers on the group. But a generation or so hence, how many of these will be anything but meaningless names to students of the subject?

---

[1] Jour. Trop. Med., xxi., 1918, p. 221.

nd now it is proposed to inflict on us *Lewisonella*, *astellanella*, *Duttonella*, &c.! So far as I am aware, rofessor Minchin never created a personal generic ame in the whole course of his scientific research. The small amœboid parasite, *Malpighiella refringens*, f the rat-flea furnishes only an apparent exception, ecause it was named after its habitat in the excretory rgans, generally known as the Malpighian tubules.)

Helminthologists are much less prone to this bad abit than are, unfortunately, certain protozoologists. write subject to correction, as I have been away uring some years, but I do not think that helminthology burdened with such names as *Leiperia* or *Leiperella*, *icollina*, *Stewartia*, and so on. Apart from the well-nown parasite, which was commonly referred to in the .E.F. as the "Bill Harris" (and even in regard to this does not appear to be certain that *Schistosoma* is not iore correct), there are very few of the important arasitic worms whose generic name is based upon a roper name. Among the protozoa, *Laverania* and *eishmania*, for instance, are well-established and idely known, and no objection can now be taken them on the ground of their personal character. ut I do wish to make an earnest appeal to those terested in the study of protozoa to refrain in the iture from lavish use of proper names for new genera.

More latitude may perhaps be allowed as regards the se of personal names in the formation of new species. hough here also, I know that Professor Minchin expressed himself strongly on more than one occasion in cent years in favour of using, for instance, the name the host, or of the locality in which it is prevalent, a suitable specific name for a new parasite. In the st record I compiled I had to include the following ew species of parasite created by Yakimoff:—*Prowakia* [= really, *Bodo*] *ninæ-kohl-yakimovi*, *Trichomonas næ-kohl-yakimovi* and *Trypanoplasma ninæ-kohl-yakiovi!* Mme. N. Kohl-Yakimova is an excellent partner; it I think it would have sufficed to commemorate her ıme in the case of one new species alone.

The very height of absurdity, however, is reached hen a personal name and a scientific term are ited into one compound word. What does "*Trypostellanelleæ*" mean? Is "Trypo" a contraction for Trypano"? Are we henceforth to think of this tribe parasites as, primarily, corkscrew-shaped, little stellanis? One could imagine that Chalmers must ıve felt acutely disappointed that he was precluded om introducing us also to a little Chagas, dividing by ultiple fission ("*Schizochagasella*") or to a little esnil, living somewhere internally ("*Endomesnilella*"). ut I am afraid that Chalmers can have no sense of ımour. Seriously, the thing is ridiculous, if I may so press myself. As a matter of fact, one of the recomendations appended to Art. 8 of the Code of Intertional Rules of Zoological Nomenclature runs thus: Les noms propres ne doivent pas entrer dans la rmation des mots composés"; or, as the English rsion puts it: "The use of proper names in the rmation of compound generic names is objectionable." is—distinctly.

Fortunately, in my opinion, some, at any rate, of the w generic names proposed by Chalmers have no lidity. Admitting, for present purposes, that the fferent types of trypanosome are to be subdivided ıong different genera along the lines suggested, ıalmers appears to have arbitrarily created names thout any reference to the nomenclatural history of e genus. Now Doflein, in 1901,[2] separated *Trypanosoma visi*, *brucei*, and other forms from the trypanosome of gs (*T. rotatorium*), as a distinct sub-genus, to which gave the name *Herpetosoma*. If, then, the first-med forms are now to be regarded as possessing neric rank, the sub-generic name *Herpetosoma* has iority and becomes raised to the rank of genus, the pe species being *Herpetosoma lewisi* of the rat. Art. 7 the International Code runs thus: "Un nom générique sse au rang de nom sub-générique quand le genre sse au rang de sousgenre, et réciproquement." ıerefore, Lühe had no right to ignore Doflein's name *Herpetosoma* when, in 1906, he proposed the generic name *Trypanozoon* for mammalian trypanosomes.[3] For the time being *Trypanozoon* became a synonym. If, however, it is now considered preferable to remove the pathogenic mammalian forms from the genus containing *lewisi* and associated parasites of small rodents, we can correctly and most fittingly restore the name *Trypanozoon* for the former; it is, at any rate, much more suitable than *Castellanella*. We should have then *Trypanozoon gambiense*, *brucei*, *evansi*, &c. There is therefore, I think, no justification for *Lewisonella* and *Castellanella*. I fear I cannot at present facilitate, likewise, the *exit* of *Duttonella*; but perhaps some authority on spirochætes can assist? To complete the enumeration, it may be added that, if the trypanosomes of fishes are generically distinct from *T. rotatorium*, their generic name should be *Hæmatomonas*, Mitrophanow, 1884 (this name was adopted by Lühe). And if those of birds are again distinct, their generic name should be *Trypanomorpha*, given by me to the trypanosome of the little owl (*T. noctuæ*) in 1906.

One further point in conclusion. Chalmers separates the Uganda parasite of sleeping sickness from Dutton's form *T. gambiense*, as a distinct species, *T. castellanii*. As I pointed out at the time,[4] and again in my article on the Hæmoflagellates,[5] the specific name *castellanii*, Kruse, is in any case a synonym, antedated by the name given by Castellani himself, when he made known his most important discovery of the parasites in the cerebro-spinal fluid—viz., *ugandense*—"from the country where I found it first." If the suggested separation of this form is adopted, its correct specific name is *ugandense*; and we then have the useful series —*gambiense*, *ugandense*, *rhodesiense*, and *nigeriense*.

It is greatly to be regretted that an interesting paper like this by Chalmers should lose much of its attractiveness by reason of its errors, both of commission and omission, in regard to the nomenclature. It is, indeed, to be hoped, however, that in the next edition of the "Manual of Tropical Medicine," these will not be repeated.

I am, Sir, yours faithfully,

H. M. WOODCOCK.

Lister Institute of Preventive
Medicine, S.W., Feb. 14th, 1920.

CIRCUMCISION AND CONGENITAL HYPERTROPHIC STENOSIS OF THE PYLORUS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Sept. 20th, 1919, you published a most interesting and suggestive study of congenital hypertrophic stenosis of the pylorus by Mr. H. Tyrrell Gray and Dr. G. R. Pirie, in which reference was made to a possible causal connexion between the presence of phimosis, or preputial adhesions, and the vomiting associated with this malformation of the pylorus in infants. As I understand it, these writers suggest that phimosis may be responsible for the additional spasm which causes a tumid pylorus to block the outlet of the stomach, or it may cause spasm in a healthy pylorus which gives rise to the same clinical phenomena. In both cases the adherent prepuce acts as a source of irritation to the adrenals, and the consequent hyperadrenalism may lead to hypertonus of the pyloric sphincter, whether a tumour be present or not.

A recent case admitted to the East London Hospital under my care seems partially to bear out their contention, which they supported by instances of cessation of projectile vomiting after circumcision. The patient was a boy, aged 5 weeks, with a two weeks' history of vomiting, wasting, and constipation. On admission the child was emaciated and wizened; the vomiting was so projectile in character that, I am told, it was forced some 6 feet away from the infant. Gastric peristalsis was easily observable, but there was some doubt as to whether a pyloric tumour could or could not be felt. The penis was examined and the prepuce could not be withdrawn over the glans. I examined the child on the day after admission with a view to operation, but his condition was so pitiable that I hesitated to do

any abdominal operation, even Rammstedt's, which can easily be finished in a few minutes. It therefore occurred to me to test the value of circumcision. The child was accordingly anæsthetised by the open-ether method, and we took the opportunity of palpating the abdomen. No pyloric tumour could be felt. Circumcision was done, and we were delighted to find that all vomiting ceased and the child began to put on weight—for a week. At the end of this period projectile vomiting again occurred and visible peristalsis was seen. I re-examined the child, and, after due inquiry, came to the conclusion that the recurrence of vomiting could be explained by the fact that the feeds were too large. These were reduced in amount and peptonised milk was given. A further week of apparent prosperity ensued, and then the child refused its feeds and suddenly died.

The post-mortem examination revealed no pyloric tumour, no gastritis, and no obvious cause of death except slight broncho-pneumonia. There were no strictures in any part of the alimentary tract.

This case appears to be strictly comparable to those recorded by Mr. Gray and Dr. Pirie where circumcision has had a beneficial effect on pyloric spasm. However, the fact of recurrence of projectile vomiting, amenable to alteration in the character and amount of the feeds, suggests that other factors are present which one cannot expect to alter by the removal of the adherent prepuce.

I am, Sir, yours faithfully,
Devonshire-place, W., Feb. 12th, 1920. JOSEPH E. ADAMS.

LOCAL ANÆSTHETICS IN INTESTINAL OBSTRUCTION.

To the Editor of THE LANCET.

SIR,—I have noticed that in operations for the relief of intestinal obstruction the vomiting which generally follows the anæsthetic contains stercoraceous material, which during the act becomes drawn into the air-passages. I have therefore decided not to give general anæsthetics in these operations. Indeed, I have carried out many abdominal sections with no anæsthetic; very little pain is caused, and local anæsthetics, such as freezing with ether or ethyl chloride, or the hypodermic injection of β-eucaine, are quite sufficient. By following this suggestion I feel that lives would be saved which now are lost from acute bronchitis.

I am, Sir, yours faithfully,
Deal, Feb. 17th. THOMAS H. MORSE.

IS THERE A PARA-SCARLET FEVER?

To the Editor of THE LANCET.

SIR,—In a letter which appeared in your issue of Feb. 7th Dr. Frederic Thomson asks the reasons for my belief that certain cases of mild scarlet fever were not cases of rubella. Let me make it clear that my statement referred only to cases which had been under my observation during the present epidemic, and not to mild scarlet fever in general. I should be the last to assert that the differentiation of mild scarlet fever from rubella is always possible, although I do believe that the number of instances in which confusion is inevitable should be small.

Part of the answer to Dr. Thomson's query is given by Dr. E. W. Goodall in his letter last week, where he says, "rubella has not been prevalent in London lately, nor is it now," an experience with which I am in complete agreement. Neither have these patients caused any outbreak of rubella in our scarlet fever wards; not a single case of this disease has occurred. Additional arguments are the facts that none have shown catarrhal symptoms, none have presented preponderating enlargement of the mastoid or occipital glands, none have shown an eruption of measly character on the face, limbs, or elsewhere; and where complications have occurred they have been those associated with scarlet fever—i.e., otitis media and cervical adenitis. The raw peeled tongue has been very evident on the fourth day, and typical desquamation has appeared in due course in nearly all cases; this desquamation has reappeared after the second attack.

But the object of my letter was to elicit the experience of others during the present outbreak. I still hold that the number of relapses or reinfections is decidedly in excess of normal, as also is the number of patients who give a history of a previous attack of scarlet fever. Evidently Dr. Goodall cannot corroborate me, but I should like to have some further expressions of opinion. Dr. Goodall will notice that I have taken to heart his reproof with regard to the term German measles; it is justified.

I am, Sir, yours faithfully,
Devonshire-place, W., Feb. 16th, 1920. CHARLES R. BOX.

MEDICAL PRACTICE IN A TRANSITIONAL PERIOD.

To the Editor of THE LANCET.

SIR,—In a leading article in your issue of Feb. 7th you allude to the present very truly as a transitional period of medical practice. Several thousand medical men have returned home after periods of service in the R.A.M.C. with a very different vision of the future of civil medical work. They have learned a good deal to avoid, but they have also learned much they will be willing and anxious to incorporate in any future scheme of medical service. One lesson learned is the value of coöperation. That is a point which does not need to be laboured. My wish is to deal with another matter altogether. Medical officers have not only seen service with units of different kinds, field ambulances, base hospitals, &c., but in many cases have had special courses of training. This tends to an all-round knowledge lacking in the civil general practitioner without these experiences. In the R.A.M.C., among both officers and men, high specialisation is rather discouraged than encouraged. At first sight this looks on a par with general army inefficiency, as compared, for example, with a civil business of vast dimensions. But five years' acquaintance with the R.A.M.C., and the prospect of a return to civil practice, leads me to take another view.

I qualified over 20 years ago, and since then there have been many and huge advances in medicine and allied sciences. What has been the effect on the general practitioner, who makes up the bulk of the profession? Little by little his work has been, and is still being taken from him, and passed into the hands of specialists working for public bodies, until he is becoming something less than the old apothecary. The establishment of tuberculosis clinics, venereal clinics, infant welfare clinics, &c. (the process is steadily continuing) are nothing more than an open implication that the general practitioner does not know his work and is not to be trusted with these matters. Many years ago I consulted a solicitor for the first, and I hope the last, time I put the details before him and asked him if it was a good enough case to take to court. His reply was: " must take counsel's opinion." That is what the general practitioner is coming to. No doubt in the future when he is called to a bedside he will take the temperature and feel the pulse and remark: "Ah, this is a case for a lung specialist," or a heart specialist, or any other specialist, so long as he is not expected to make a diagnosis himself or treat the case on his own responsibility.

Now, who or what is responsible for this position Partly the scramble for a living, which makes the unfortunate practitioner take a huge list of panel and similar patients, and compels him to "get through" a crowd of 50 or 60 patients in an evening surgery of an hour and a half. That is a point which must be remedied in any future scheme of medical service. But far more than that the responsibility lies at the door of those responsible for medical education. The present student is overloaded with a lot of perfectly useless stuff: there is a hopeless waste of time in lectures on subjects which cannot be taught by lectures, and provision for post-graduate work, without which a man soon drops behind, is only now being talked about as a general necessity.

For qualification purposes there should be one standard throughout the country for a pass examination, and this should represent the minimum requir nents for a general practitioner—I know how often his has been discussed. Let the examining bodies ave their D.P.H.'s, their diplomas in radiology, athology, and what not, for those to take who lesire. For a pass examination no man would be sked such absurd questions as "Discuss the theories f hyperpyrexia," as I was asked. Nor should obscure ervous diseases be given him to diagnose in his linical examination. But he would be expected to be ble to diagnose early pulmonary tuberculosis without aving to send round for the tuberculosis expert, and to now how to administer "606" without the aid of the enereal expert. Every man should be taught that the nicroscope, including the dark-ground condenser, is as ecessary a part of a practitioner's equipment as a linical thermometer or a stethoscope. Also he should e able to do simple serological tests like the Widal. I now this is poaching on the preserve of the specialist, ut, after all, is it not better to have 1000 men with a ood all-round knowledge than one highly technical xpert and 999 ignorant men?

To teach these things, not as a matter of academic nterest, but as being necessary to the medical man's uture work, would mean a drastic overhaul of the nedical curriculum. Such subjects as toxicology and nateria medica should be ruthlessly thrown overboard. ectures on anatomy and systematic medicine and urgery are a waste of both the lecturer's and the tudent's time. Generally speaking, lectures which annot be illustrated by experiments or by clinical xamples should be cut out. Anatomy can be taught y a good prosector dissecting before a small group of ix men much better than by a professor with a vonderful memory and marvellous diagrams. Similarly, athology can be much better taught in the laboratory han in the lecture-room. The lectures on surgery that listened to were read verbatim; with a text-book efore me I could have made as good a professor. inally, post-graduate work ought to be compulsory, ut at the present time not one man in a hundred an afford the expense of a locum-tenent while he takes ut a post-graduate course which he also has to pay for.

These, Sir, are a few ideas which I think need iscussion in the transitional period. I have no axe to rind. The form of the future medical service is of econdary importance, but whatever its form I do feel hat the medical man of the future should be able to iagnose and treat all the common diseases (and surely uberculosis and venereal disease are among these) vithout having recourse to an army of experts, some of vhom are only experts in name after all.

I am Sir, yours faithfully,

Feb. 11th, 1920. P. H. A.

⁂ Our correspondent covers much ground which as formed the subject of discussion, such as the overoading of the medical curriculum, the advantages of a ne-portal system, and the necessity for post-graduate evision of knowledge. But his wish to ensure that the eneral practitioner, properly trained, shall have full hances of success will be seconded by all.—ED. L.

DILEMMA AT COLEFORD: RESIGNATION OF THE NLY PANEL DOCTOR.—At the last meeting of the Frome Somerset) board of guardians the relieving officer reported hat at Coleford, a large village near Bath, owing to the esignation of a medical practitioner, there was no panel loctor resident there. He understood that the county ouncil had informed the insured persons, who required nedical advice, that their expenses in consulting medical nen would be refunded. The guardians decided that they ould do nothing in the matter.

DEATH OF DR. W. C. LAKE.—William Charles Lake, M.D. St. Andrews, M.R.C.S., L.S.A., died recently at his residence, Teignmouth, Devon, in his ninety-fifth year. The deceased, the son of a surgeon in the Royal Navy, had practised in Teignmouth for over 40 years. He was on the honorary medical staff of the Teignmouth Hospital, for 14 years was medical officer of health for the urban district, and performed much useful work during the outbreak of cholera in 1867. Dr. Lake was highly esteemed and respected at Teignmouth, and when he retired in 1891 was the recipient of a public presentation.

Medical News.

UNIVERSITY OF CAMBRIDGE: DIPLOMA OF PSYCHOLOGICAL MEDICINE.—Courses in preparation for both parts of the diploma are being arranged at the Maudsley Hospital, London, in the afternoons, beginning early in March. Sir Frederick Mott, Dr. F. Golla, Dr. J. P. Lowson, Dr. C. H. Bond, Sir H. Bryan Donkin, Dr. F. C. Shrubsall, Dr. W. MacDougall, and Dr. Bernard Hart will take part in tuition. Dates and hours to be announced later.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At a meeting of Comitia of the Royal College of Physicians on Jan. 29th, and of the Council of the Royal College of Surgeons on Feb. 12th, diplomas of L.R.C.P. and M.R.C.S. were respectively conferred upon the following 67 candidates (including 7 women) who have passed the requisite examinations and have complied with the by-laws of the Colleges:—

Mohamed Khalil Abdel-Khalik, Cairo and Middlesex Hosp.; Henry Edwards Archer, St. Bart.'s Hosp.; Hubertus Adriaan Moorrees Bosman, Heidelberg Univ.; Doris Irene Bosworth, Birmingham Univ.; Percy James Briggs, Cambridge Univ. and Guy's Hosp.; Elliott Fraser Brown, Birmingham Univ.; Joseph Henderson Bulcock, Manchester Univ.; Harold George Burford, Oxford Univ. and Guy's Hosp.; George Frederic Burnell, Charing Cross Hosp.; Frederick Wyndham Chamberlain, Middlesex Hosp.; Gilbert Leedham Clements, Birmingham Univ.; Maurice Coburn, Guy's Hosp.; John Joseph Coghlan, London Hosp.; Bernard Hedley Cole, Cambridge Univ. and St. Bart.'s Hosp.; Alison Margaret Collie, St. Mary's Hosp.; Arthur Cedric Mears Coxon, Cambridge Univ. and Guy's Hosp.; Geoffrey Wright Dando, Birmingham Univ.; Andrew Norman Macdonald Davidson, King's Coll. Hosp.; Charles Owen Davies, Liverpool Univ.; David Justin Davies, Middlesex Hosp.; Thomas Draper, Edinburgh Univ.; William Edge, London Hosp.; Isaac Frost, St. Bart.'s Hosp.; Lawrence Paul Garrod, Cambridge Univ. and St. Bart.'s Hosp.; Mary Isabel Alleyne Grimmer, Durham Univ. and Charing Cross Hosp.; Edward Anthony Hawke Grylls, Cambridge Univ. and London Hosp.; George Cleverdon Hartley, Birmingham Univ., Frank Sutcliffe Horrocks, Manchester Univ.; Charles Arundel Hutchinson, London Hosp.; Evelyn Hope Johnson, Manchester Univ.; Oswald Edward Kennedy, Queen's Univ., Kingston, and London Hosp.: Joseph Victor Landau, St. Bart.'s Hosp.; Frank Fawckner Langridge, London Hosp.; Gordon Parmiter Lindsay, Guy's Hosp.; Patrick Thomas McIlroy, Queen's Univ., Kingston; Syed Francis Mahmood, St. Bart.'s Hosp.; Ida Caroline Mann, Royal Free and St. Mary's Hosp.; Grant Massie, Guy's Hosp.; Tete Mensa-Annan, Cambridge Univ. and King's Coll. Hosp.; Oscar Gerald Misquith, Cambridge Univ. and St. George's Hosp.; Abdel Wahhab Mooro, Cairo and St. Bart.'s Hosp.; Clement Nicory, St. Thomas's Hosp.; Francis Ambrose O'Reilly, Queen's Univ., Kingston, and Charing Cross Hosp.; Spencer Tauria Parker, Otago Univ.; Edgar Francis Jones Peregrine, Cardiff and St. Mary's Hosp.; *George Perkins, Oxford Univ. and St. Thomas's Hosp.; *Hugh Hamilton Perry, Manitoba Univ. and London Hosp.; Norman August Marais Petersen, London Hosp.; Gosford James Preston, Queen's Univ., Kingston, and Charing Cross Hosp.; Leonard Ignatius Roberts, Univ. Coll. Hosp.; Roland Ephraim Rawson Sanderson, Cambridge Univ. and St. Bart.'s Hosp.; Harry Norman Schapiro, Guy's Hosp.; Frank Paul Schofield, Campbell Shaw, and Gerald Maurice Joseph Slot, St. Bart.'s Hosp.; Syed Sarwar Hussain Sofi, Hyderabad and London Hosp.; Saravanamuttu Somasundram, Ceylon and Middlesex Hosp.; Stephen Douglas Sturton, Cambridge Univ. and St. Bart.'s Hosp.; Walter Aslatt Turner, Guy's Hosp.; †Kathleen Suzanne Vine, Royal Free Hosp.; Norman Victor Wadsworth, Guy's Hosp.; Alfred Douglas Weeden, Middlesex Hosp.; Clement John Lethbridge Wells and John Stanley White, St. Bart.'s Hosp.; Kathleen Mary Wilkinson, Birmingham Univ.; Donald Woods Winnicott, Cambridge Univ. and St. Bart.'s Hosp.; and Jane Edith Wood, Leeds Univ.

* Diploma of M.R.C.S. conferred on Nov. 11th last.

† Diploma of M.R.C.S. alone conferred.

The Diploma in Public Health was also conferred (in conjunction with the Royal College of Surgeons) upon the 15 candidates whose names were published in THE LANCET of Feb. 14th, p. 405.—It was decided to hold an examination in Public Health, Parts I. and II., in April next, commencing on the 19th and 26th respectively.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—An ordinary meeting of the Council was held on Feb. 12th, Sir George H. Makins, the President, being in the chair.—It was resolved to grant diplomas of Membership to 65 successful candidates; and diplomas in Public Health were granted to 15 candidates, in conjunction with the Royal College of Physicians of London.—Mr. John Murray was re-elected a Member of the Court of Examiners.—It was resolved to grant the honorary Fellowship to the following surgeons: M. A. Depage, Surgeon to His Majesty the King of the Belgians; M. Pierre Duval, Professeur à la Faculté de Médecine de Paris; Professor J. M. T. Finney, Professor of Surgery, Johns Hopkins University; M. A. Gosset, Professeur à la Faculté de Médecine de Paris; Professor Charles H. Mayo, Professor of Surgery, Mayo Foundation for Medical Education and Research, University of

Minnesota.—It was resolved that the presentation of the diplomas to the newly elected honorary Fellows should take place on July 8th next.—Dr. W. S. A. Griffith was reappointed the representative of the College on the Central Midwives Board for the period of one year, and the best thanks of the Council were given him for his services on that Board during the past year.—The President reported that he had reappointed Mr. William F. Haslam the representative of the College on the medical board of the University of Wales for three years.—The President reported that in pursuance of the provisions of the Bradshaw bequest he had appointed Sir Berkeley Moynihan as Bradshaw lecturer for the ensuing year.—In accordance with a report from the Committee of Management, certain alterations in the conditions for the examinations in Tropical Medicine were approved and adopted. It was also approved that the Committee of Management should be requested to report on the subject of special diplomas, with appropriate regulations for curriculum and examination in each of the subjects to be dealt with.—A committee to consider the question of the representation of Members of the College on the Council was elected.—The President reported that a meeting of Fellows would be held at the College on Thursday, July 1st next, for the purpose of electing three Fellows into the Council in the vacancies occasioned by the retirement in rotation of Sir Anthony A. Bowlby, Mr. W. Harrison Cripps, and Sir D'Arcy Power. The last day for the nomination of candidates will be March 15th. A voting paper will be sent to every Fellow whose address is registered at the College.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH: MORISON LECTURES.—The Morison Lectures will be delivered before the Royal College of Physicians of Edinburgh by Dr. R. Gundry Rows, C.B.E., on Monday, Wednesday, and Friday, March 1st, 3rd, and 5th, 1920, at 5 P.M. The subject of the lectures is announced as Mental Illnesses.

THE TUBERCULOSIS SOCIETY.—A general meeting of the society will be held at the rooms of the Medical Society, 11, Chandos-street, Cavendish-square, to-day, Saturday, Feb. 21st, at 8 P.M., when Dr. Halliday Sutherland will open a discussion on "The Need for a Diploma in Tuberculosis."

UNIVERSITY OF BRISTOL.—At examinations held recently the following candidates were successful:—

FINAL EXAMINATION FOR THE DEGREES OF M.B., CH.B.

Part II. (completing examination).—Bernard Archibald Astley-Weston, Hilda Mary Brown, Daniel Gingell Cossham, Sukhasagar Datta, and Frederick Viel Jacques.

Part I. only.—Khai Way Chan, Marjorie Wadsworth.

SECOND EXAMINATION FOR THE DEGREE OF B.D.S.

George Norman Beason.

SECOND EXAMINATION FOR THE DIPLOMA IN DENTAL SURGERY.

William Bayly, Leslie Clifford Bodey, and Evan Elwyn Lewis.

EXAMINATION FOR THE DIPLOMA IN PUBLIC HEALTH.

Walter Henderson Scott.

UNIVERSITY OF LONDON.—Dr. Herbert Eldon Roaf has been appointed to the University Chair of Physiology tenable at the London Hospital Medical College, and Professor Thomas Swale Vincent to the University Chair of Physiology tenable at the Middlessex Hospital Medical School.—The Senate has passed a resolution expressing appreciation of the generosity of Messrs. S. B. and J. B. Joel in presenting £20,000 for the endowment of a University Chair of Physics tenable at the Middlesex Hospital Medical School. Steps are being taken immediately for the appointment of the first incumbent of this professorship, which will bear the name of the donors.—A University Studentship in Physiology, of the value of £50 for one year, will be awarded to a student qualified to undertake research in physiology and will be tenable in a physiological laboratory of the University or of a school of the University. It will be awarded annually if a candidate of sufficient merit presents himself. A student will not be eligible for re-election, and candidates must be matriculated students or graduates of the University and must submit a statement of their qualifications and the names of three referees. Applications must be made on or before May 31st.—The University medal in Branch I. (Surgery) of the M.S. Examination for internal and external students, December, 1919, has been awarded to Edward Gustave Slesinger, B.Sc., of Guy's Hospital.—Fifteen medical entrance scholarships and exhibitions of an aggregate total value of about £1260, tenable in the Faculty of Medical Sciences of University College and King's College and in the medical schools of Westminster Hospital, King's College Hospital, University College Hospital, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital, will be offered for competition on June 29th, 1920. Full particulars may be obtained from the secretary of the Board, S. C. Ranner, M.A., Medical School, King's College Hospital, Denmark Hill, London, S.E.5.

CAPETOWN UNIVERSITY MEDICAL FACULTY.—Professor Crichton, a graduate of Dublin University, has been appointed to the Chair of Obstetrics and Gynæcology in the University of Capetown. He has studied in Dublin, Berlin, and Heidelberg, and has held the position of external maternity assistant at the Rotunda Hospital, and later that of assistant master of this hospital. He served during the war in the R.A.M.C. as surgeon in the 1st Eastern General Hospital, and with the Egyptian Expeditionary Force, and was mentioned in despatches in 1917. The institution of this chair, together with the previous appointments to the chairs of medicine and surgery, represents a further stage in the organisation of the Medical Faculty of the Capetown University, and enables the University to complete this year the necessary arrangements for a full medical undergraduate curriculum and the granting of degrees in medicine and surgery. A post-graduate course in public health will be instituted this year also, and will lead to a University Diploma in Public Health, corresponding to that granted by many British Universities and regarded as an essential qualification for medical men who are engaged in public health services.

MIDDLESEX HOSPITAL MEDICAL SCHOOL.—Emeritus Lectures will be delivered at the school on Feb. 26th by Sir Alfred Pearce Gould, and on March 5th by Sir Richard Douglas Powell. The lectures will be delivered at 3 P.M.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The annual dinner of past and present students of the Royal London Ophthalmic Hospital will be held at the Criterion Restaurant, Piccadilly, on Thursday, March 11th, at 7 for 7.30 o'clock, Mr. William Lang, consulting surgeon to the hospital, presiding. Those intending to be present should communicate as soon as possible with Mr. Charles Goulden, 42, Welbeck-street, London, W.1.

NO. 19 CASUALTY CLEARING STATION.—It is proposed to hold a 19 C.C.S. dinner in London on Saturday, Feb. 28th, at the Trocadero Restaurant, Piccadilly Circus, W., at 7.30 P.M., when it is hoped that many officers of the unit will be able to be present, while members of other C.C.S.'s and all who were associated with the station are cordially invited to attend. Applications for tickets should be made as soon as possible to the Rev. E. C. Doddrell, at 6, Alexandra House, Regent's Park-road, N. 3.

WORKERS FOR SERBIA.—A dinner will be held on Monday, March 1st, at 7 for 7.30 P.M., at the Wharncliffe Rooms, Great Central Hotel, to give an opportunity for social re-union to those who have worked during the war on behalf of Serbia. The committee of the dinner, which is widely representative of those who have served abroad for the Serbians, announce that already tickets have been taken by men and women associated with most of the medical missions or with the motor transport attached to the Royal Serbian Army. They also call attention to the fact that at this Service dinner men and women are alike eligible as participants. Tickets, 15*s.* each (exclusive of wine), may be obtained from the honorary secretary, Miss Marx, 24, Melcombe-court, Dorset-square, N.W.1.

RESIDENTIAL TUBERCULOSIS TREATMENT: A CONFERENCE OF MEDICAL OFFICERS.—A conference of the medical superintendents of sanatoriums, training colonies, and other residential institutions for cases of tuberculosis has been called for Monday, Feb. 23rd, 4 P.M., at 122, Harley-street, to discuss the problems which specially concern such institutions. The invitation to this conference is signed by Dr. Esther Carling (Peppard), Mr. E. H. T. Nash (Preston Hall), Dr. A. Niven Robertson (Benenden), Mr. P. C. Varrier-Jones (Papworth Hall), Dr. Jane Walker (Nayland), Dr. James Watt (Downs, Sutton), and Dr. R. C. Wingfield (Frimley), and states that there is at present no recognised body of medical men or women to whom to turn for the advancement of the institutional treatment of tuberculosis. Many new problems are arising, and it is felt that there ought to be some means of communication and discussion between medical men and women specially interested in this work. By such means experiences can be exchanged, new ideas on treatment and administration brought forward and sifted, certain standards set up and recognised as essential in the residential treatment of tuberculosis, and greater weight given to individual recommendations which have received the approval of a body of expert opinion. Through the action of a vigorous society, an impetus can be given to the improvement of administrative and therapeutic methods. The subjects likely to come up for discussion at this conference are the appointment of a special committee to consider and report on the standards of treatment to be aimed at in institutions for tuberculosis; sanatorium nurses in relation to general training; the treatment of advanced and dying cases; and the granting of leave to patients at holiday times. Quarterly meetings are suggested.

The Society of Apothecaries has awarded the Gillson scholarship for original research in pathology of the annual value of £105 to Dr. A. L. Urquhart, of St. Thomas's Hospital.

National Health Week.—The Lord Mayor, in his capacity [redacted] chairman of the National Health Week Committee, appointed by the Royal Sanitary Institute, has received letters from the King and Queen acceding to a request for Royal patronage of the 1920 celebration of Health Week, which has been arranged to take place throughout the country from May 2nd to the 8th.

Hygiene as a Remedy for Social Unrest.—A lecture on this subject was delivered at the Institute of Hygiene on Feb. 11th by Mr. Grant Ramsay, F.R.E.S., Principal of the Institute, Sir Arthur Yapp in the chair. Mr. Ramsay said that two peaceful revolutions were prominent to-day: the labour cause, and woman's "so-called emancipation." The one affected the country's future and the other the future race, but both were going too fast. There was good reason for shorter hours at the present time, and even six hours a day was too long for certain classes of work, but with better organisation, better feeding, better housing, and change in work there was no reason why any fit man should not do 12 hours a day. That might be called intensive labour, and would require to be entered upon in courses and in the spirit of a good dinner, but it would benefit the worker himself and greatly help the country. The woman's movement was marked less by emancipation than by climbing down to the level of men, but, while the disproportion of the sexes remained, justice demanded that every vocation should be free and open to them. The primary duty was maternity. The lecturer had investigated the question of the falling birth-rate in France 30 years ago, and had concluded that the chief cause affecting maternity was the psychological influence traceable to the degree in which French women shared their husbands' worries in business as well as in the home. Excitement and gaiety also adversely affected the birth-rate. Hygiene was a very sound remedy for social unrest, as the principles of hygiene require moderation in all things, and never was moderation so necessary as now. The country was a great invalid requiring every care in convalescence, and those who were dancing mad and living riotously were simply patients in a state of delirium. Steady work and sobriety in living was the great panacea, and we could not have real peace until we settled down.

Reconstruction of Clinical Teaching: the Position at St. Bartholomew's Hospital.—The reorganisation of clinical teaching at St. Bartholomew's Hospital is now approaching completion. As we have already announced, two professorial clinical units began their work on Oct. 1st. The director of the medical unit is Sir Archibald Garrod, the assistant director Dr. F. R. Fraser, and the chief assistants Dr. A. E. Gow and Dr. George Graham. Dr. Fraser, son of the late Sir Thomas Fraser, was educated at Cambridge and Edinburgh, and was recently consulting physician to the British Army at Cologne. He has held the posts of assistant physician to the Presbyterian Hospital, New York, instructor in clinical medicine at the Columbia University, and assistant resident physician to the Rockefeller Institute for Medical Research. He took up his duties at St. Bartholomew's on Feb. 1st, and his appointment completes the medical unit there. The surgical unit is under the direction of Mr. George E. Gask, and the post of assistant director has recently been filled by the appointment of Mr. T. P. Dunhill, surgeon to the St. Vincent's Hospital, Melbourne, who during the war acted [redacted] a consulting surgeon to the British Army in France. The chief assistants are Mr. R. Ogier Ward and Mr. G. L. Keynes. Each of these units is provided with clinical laboratories of its own for routine pathological work and research. They each take their share of the ordinary hospital duties, and are linked up so as to be in daily communication and consultation. Not only have these units been set up, in which the directors are devoting their whole time to the duties of teaching and research, but the other medical and surgical clinics have been reconstituted by the appointment to each of a chief assistant who acts [redacted] registrar to his unit, supervises the routine clinical pathology connected with it, and gives instruction to the students in this work. The pathological department has undergone reconstruction. In addition to Professor F. W. Andrewes, who is head of the department, Dr. M. H. Gordon is bacteriologist to the hospital and lecturer on bacteriology; Dr. B. H. Spilsbury supervises the post-mortem examinations and is lecturer on morbid anatomy and histology; and Dr. R. L. Mackenzie Wallis is chemical pathologist to the hospital and lecturer on chemical pathology. Three senior demonstrators have been appointed as whole-time pathologists and, in addition, three junior demonstrators as part-time officers.

Royal Medical Benevolent Fund.—At the last meeting of the Committee, held on Feb. 10th, 17 cases were considered and £183 2*s*. voted to 14 of the applicants. The following is a summary of some of the cases relieved:—

Widow, aged 38, of M.D. Dub. who practised in Dublin. Applicant is a trained nurse, but is unable to work at present on account of ill-health of self and child. Pays 5*s*. a week rent for one room. Relieved four times, £29. Voted £10.—Widow, aged 38, of L.R.C.P. Edin. who practised at Battersea and died in 1917. Has been living on her capital, which is now entirely exhausted. Has three children, ages 12, 10, and 4, and is without means, and two of the children are ill. Has been living for some time on the sale of her furniture, as she cannot take a situation on account of the children. Rent 17*s*. for two rooms. Relieved once, £10. Voted £5 and a special grant of £2 2*s*.—Widow, aged 61, of L.S.A. Lond. who practised at Limehouse and died in 1894. Was left unprovided for with two daughters, now aged 27 and 26. The elder one earns £60 a year and the younger £40, and between them they pay their mother £60. Applicant earns £13 by needlework. Rent and rates £35. Relieved 12 times, £140. Voted £18 in 12 instalments.—Daughter, aged 58, of F.R.C.S. Eng. who practised in Bedfordshire and died in 1890. Has no income. She receives £13 from the Guild. Rent 4*s*. a week. Relieved 14 times, £136. Voted £18 in four instalments.—Daughter, aged 57, of M.R.C.S. Eng. who practised at Hadleigh and died in 1877. Applicant received £18 from dividends and £21 from another charity. Does a little needlework occasionally. Rent 10*s*. 6*d*. for two rooms. Relieved four times, £38. Voted £18 in 12 instalments.—Daughter, aged 73, of L.S.A. Lond. who practised at Christchurch and died in 1880. Only certain income £47 from dividends. Applicant is an artist and occasionally sells a picture. Pays £3 per week for board and lodging. Relieved four times, £63. Voted £9 in six instalments.—Daughter, aged 61, of M.D. Lond. who practised in North London and died in 1868. Acts as housekeeper or does a little nursing when her health permits. Receives £26 from another charity and £12 from friends. Rent 10*s*. a week for one room. Relieved six times, £36. Voted £12 in 12 instalments, and a special grant of £2.—Daughter, aged 61, of M.R.C.S. Eng. who practised at Sheffield and died in 1867. At present she has a temporary post as a clerk at £65 a year, but this may cease at any time. Only other income £30 from another charity. Cannot manage owing to the high cost of living. Board and lodging 26*s*. a week. Relieved twice, £24. Voted £12 in 12 instalments.—Widow, aged 70, of M.R.C.S. Eng. who practised in East London and died in 1906. Was left unprovided for with six children; four of them are now married and are unable to help. Eldest daughter is a teacher and pays the rates and taxes, £22; the other daughter helps at home. Applicant takes in boarders. Rent £38. Relieved by the Fund many years ago and again in 1913, when she was granted £12. Voted £10.

Subscriptions may be sent to the honorary treasurer, Sir Charters J. Symonds, C.B., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

Royal Victoria Hospital, Edinburgh: Tuberculosis Trust.—At the annual general meeting Mr. Charles Cook, W.S., the chairman, said that there had been a growing feeling on the part of those best entitled to speak that treatment hitherto had been directed too exclusively to the pulmonary forms of tuberculosis. It must be kept in mind that tuberculosis of the lungs [redacted] frequently a late manifestation, which might have been checked more readily had it been taken at an earlier stage. Many other parts of the body besides the lungs were prone to the attacks of tuberculosis. The modern view was that for the most part tuberculosis was contracted in childhood, and that if detected and treated early its disastrous effects in adult life would be much reduced. They had come to the conclusion that in the future they should have regard to two aspects of the subject (1) the treatment of tuberculosis in whatever organ it occurred at any age, and (2) the investigation and development of lines of treatment for all particular forms of the disease. They had decided to establish a farm colony on national lines which would be available for the prolonged care and treatment of all forms of tuberculosis in the curable stage. Preference was to be given to soldiers, sailors, and others who had contracted the disease or had it aggravated by war service, and such preference was also to be extended to their families. Thereafter admission would be given to suitable cases from all parts of Scotland. It was hoped to combine the benefits of a sanatorium and training school. With this object, and with the coöperation of the National Association for the Prevention of Tuberculosis, they had acquired the beautifully situated estate of Southfield, in the parish of Liberton, at a cost of £9400. The grounds extended to about 33 acres, and the existing house and offices would provide accommodation for approximately 40 patients.—Sir Robert Philip outlined briefly the history of the movement for the prevention of tuberculosis, and alluded to the wise policy which had led to the establishment of the farm colony, and to the good results which should be obtained therefrom. Sir Arthur Stanley, in moving the adoption of the report, after referring to the Government campaign against tuberculosis and the part which could be played by voluntary helpers, expressed the hope that by means of the international league at Geneva, established under the auspices of the Red Cross, every country of the world could obtain full information [redacted] to how disease was being treated in other countries.

THE INDUSTRIAL ORTHOPÆDIC SOCIETY.—The following appointments have been made on the honorary visiting staff of Manor House Hospital, Hampstead: Mr. Russell J. Howard, M.S., F.R.C.S. (senior surgeon), and Mr. C. Jennings Marshall, M.D., M.S., F.R.C.S.

ST. MARK'S HOSPITAL.—The Lord Mayor of London, presiding at the eighty-fourth annual meeting of St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum, City-road, in moving the adoption of the report, drew attention to the fact that £2300 are owing to the bankers, and appealed for help to wipe out that debt and to meet ordinary expenditure. During the year the hospital treated 1509 out-patients and 655 in-patients. The fact that the latter number was lower in 1919 than in 1918 was explained by the increase in serious cancer cases requiring long treatment.

PRESTON HALL COLONY.—At this Kentish tuberculosis colony, which is being run by the Industrial Settlements, Ltd., it is expected that 43 places will be available next month. The charge is to be 45*s.* a week, and each applicant must undertake to stay for a period not less than six months. Patients are admitted either directly from a sanatorium or upon the certificate of a tuberculosis officer. Only those without tubercle bacilli in their sputum are admitted.

DIPHTHERIA IN CORNWALL.—At the last meeting of the Phillack (Cornwall) urban district the medical officer of health reported that during the past month three deaths had occurred from diphtheria. There had been 19 cases of diphtheria and 4 of scarlet fever. The medical officer of health considered this a very grave state of affairs, and expressed regret that after all the expense of providing welfare nurses, &c., children should be lost through the want of proper isolation accommodation.

MANCHESTER PATHOLOGICAL SOCIETY.—Sir Walter Fletcher, secretary of the Medical Research Committee, will give an address in the Medical School of Manchester University on Tuesday, Feb. 24th, at 5 P.M., on "Medical Research after the War," to which medical practitioners and students are invited.

LIVERPOOL OVERSEAS MEDICAL OFFICERS' DINNER.—Under the chairmanship of Major-General Sir Robert Jones, K.B.E., C.B., the second annual dinner of the local overseas medical officers was held in the Exchange Hotel, Liverpool, on Feb. 13th. About one hundred were present. The toast list was a short one, and the speeches were characterised by a soldierly briefness. There was no musical programme, those present finding sufficient entertainment in reminiscences of the great days through which they had lived in every corner of the zone of war. Altogether a most enjoyable evening was spent. The back of the menu was adorned with a design by Colonel John Hay, in which, out of compliment to the chairman, Thomas's splint was a special feature.

MOBILE LABORATORY FOR THE WELSH NATIONAL SCHOOL OF MEDICINE.—The mobile laboratory originally presented to the War Office by Lady Lynn Thomas for work with the Welsh Forces in France, where it was manned by Professor E. Emrys-Roberts, has, through the timely action of these two persons, been presented by the War Office to the Welsh National School of Medicine. It is to be taken charge of by the City of Cardiff and County of Glamorgan Joint Laboratory Committee for use in public health service.

NEW HOSPITAL FOR YEOVIL.—At the recently held annual meeting of the friends of the Yeovil Hospital it was stated that plans for a new hospital had been received, and the work would shortly be commenced. The cost of the building is estimated at £30,000, exclusive of the fitting up of the institution. The committee has about £11,000 in hand, and a strong effort is to be made to obtain the necessary funds.

SHEFFIELD CORPORATION AND PARENTAL NEGLECT.—In a test case bearing on the meaning of "neglect" in the care of mental defectives recently argued in Sheffield the corporation failed to establish their claim, and judgment was given against them. A youth of 20 had been certified as mentally defective and sent to an institution. His parents, unsuccessful in their initial claim for his release, based on their dissatisfaction with his training, appealed to the law. The corporation's case depended on the interpretation of the meaning of the word neglect, as by the Mental Defectives Act of 1913 neglect is one of the reasons for which a mental defective may be placed in an institution. The court granted the parents' application, Mr. Justice Greer ruling that there was nothing in the home circumstances to justify the supposition of neglect. The case is exciting some interest, as the decision is regarded in legal circles in Sheffield as a proof that elucidation of the Act is desirable.

HONOUR FOR PROFESSOR TUFFIER.—His Majesty the King has been pleased to approve the appointment of Professor Tuffier to be an Honorary Knight Commander of the Order of the British Empire, and the appropriate insignia have been forwarded to His Majesty's Ambassador at Paris for presentation. This recognition of Professor Tuffier's services to the wounded British officers and men brought into Paris during the early phases of the war, and of his kindly and untiring efforts to make the Inter-Allied Surgical Conferences a success, will be regarded with general satisfaction by all those who enjoyed the pleasure and privilege of working in association with him. It is significant that this is an honour awarded to a temporary consulting surgeon in the civilian medical branch of a foreign nation.

CINEMA FOR HOSPITAL PATIENTS.—Through the kindness and generosity of a Brighton resident the patients of the Royal Sussex County Hospital have been given a cinematograph entertainment, which was much appreciated.

DEVON EDUCATION COMMITTEE: THE TEETH OF SCHOOL CHILDREN.—The school medical officer for the Devon Education Committee reports that in the Exeter district 693 parents (21 per cent.) refused to allow their children to be treated by the school dentist; in Plymouth 718 parents (39 per cent.) refused the treatment. Some of the members of the Committee regarded this state of things as a perfect scandal, and thought the treatment should have been made compulsory by Act of Parliament.

BRISTOL MEDICAL DRAMATIC SOCIETY.—After a lapse of six years this society has renewed its annual performance, the play chosen being *The Younger Generation*, by Stanley Houghton. The caste, which has hitherto included members of the teaching staff and a few friends not connected with the Medical School, was for the first time composed entirely of medical students, men and women. This new departure was justified by results and achieved general satisfaction. The performance was the thirty-seventh which has been given by the society.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 11TH.

Honours for Army Nurses.

Brigadier-General CROFT asked the Secretary for War whether his attention had been called to the fact that a great many trained nurses, who served as nursing sisters on active service continuously from August, 1914, onwards, had now been released from service without any official expression of gratitude for their services; whether he was aware that several cases of nurses who were recommended in the strongest terms by their commanding officers for the Royal Red Cross, First Class, in recognition of exceptional services in the actual war zone, had been passed over, whilst nurses, in many cases untrained and who never left home duty, had received this honour; and whether, in view of these facts, he would cause inquiry to be made with a view to securing justice to those who had been strongly recommended for this honour.—Mr. CHURCHILL replied: All trained nurses who served under the War Office as nursing sisters on active service have on being demobilised received an official letter conveying thanks for their services. Recommendations for the award of the Royal Red Cross, whether at home or abroad, are in all cases made by the general officer commanding under whom the person recommended has served, and so far as I am aware there have been no cases in which nurses serving abroad, who have been so recommended, have not been given the decoration.

THURSDAY, FEB. 12TH.

Vaccination Acts Amendment.

Mr. CHARLES EDWARDS asked the Minister of Health whether he would consider amending the Vaccination Acts of 1862–98 and 1907, so that compulsory vaccination and penalties for non-compliance would be repealed, and that it should be left to the parent or person having the custody of the child to determine whether or not the child should be vaccinated, without having to make a declaration before a justice of the peace.—Dr. ADDISON replied: No, Sir; the dangers to the health of the community that would be involved in the adoption of the honourable Member's suggestion are too great to admit of it being considered.

Gratuity for Army Masseuses.

Major HURST asked the Secretary for War whether masseuses of the military massage service were entitled to receive gratuities on the termination of war service; and, if not, why there should be any differentiation between them and other nursing sisters.—Sir A. WILLIAMSON replied:

War gratuities, broadly speaking, are given to commissioned fficers and enlisted soldiers and are not given to the very arge number of civilians, men and women, who in various ways worked for the army during the war. An exception to his rule was made in the case of Queen Alexandra's mperial Military Nursing Service and other staff performng similar duties, for special reasons and in accordance with precedent; but after very full consideration I am not prepared to extend this exception.

Pensions Medical Referees.

Mr. DOYLE asked the Minister of Pensions whether, in egard to War Pensions Committees, medical men could be paid for services rendered in connexion with appeal cases.—Sir L. WORTHINGTON-EVANS replied: Under the new procedure detailed in Circular 201, which was addressed to local War Pensions Committees on Dec. 23rd, the services of medical referees are no longer required in connexion with he forwarding of appeals to the Pensions Appeal Tribunals. The question of payment therefore does not now arise.

MONDAY, FEB. 16TH.

Extra Grant to Workmen's Medical Associations.

Mr. T. GRIFFITHS asked the Minister of Health if he would state why the extra grant made to medical men and chemists o meet the increased price of drugs and cost of living had not been paid out to medical men engaged by workmen's medical associations.—Dr. ADDISON (Minister of Health) replied: If the honourable Member is referring to institutions recognised under Section 15 of the Insurance Act I must refer him to the answer given on Oct. 29th to the honourable Member for West Nottingham. The Friendly Societies Medical Alliance has still failed to send in the requisite information as regards institutions in England. Information has recently come in from certain institutions n Wales, and this is under consideration with a view to determining such grants as may be due.

Dogs' Protection Bill.

Sir F. BANBURY presented a Bill "to prohibit the vivisection of dogs," which was supported by Sir J. BUTCHER and Mr. FREDERICK GREEN. The Bill was read a first time.

TUESDAY, FEB. 17TH.

Mental Cases in Military Hospitals.

Lieutenant-Colonel GUINNESS asked the Secretary for War whether, in view of the great anxiety felt by the relations of missing men owing to reports that military hospitals contained cases of such severe mental trouble that identity could not be established, he would arrange to publish photographs of all such patients in the press or otherwise, and would also collect all these cases in one hospital where they could be seen by the relatives who still had hopes of tracing men who had been reported missing.—Sir A. WILLIAMSON (Financial Secretary to the War Office) replied: There is now only one soldier of the Imperial Forces who is unidentified owing to mental trouble.

Army Medical History Sheets.

Colonel ASHLEY asked the Secretary for War whether he would consider the question of furnishing each man on discharge or demobilisation with a copy of his army medical history sheet, as the possession of this evidence would very materially assist men in establishing their statutory right to a pension.—Sir A. WILLIAMSON: Army medical history sheets are confidential, and it would be contrary to the practice of the War Office to furnish copies of them to the men concerned or to other individuals. Apart from this, the course suggested by the honourable and gallant Member would involve a great amount of additional clerical work and appears to be quite unnecessary. The medical history sheets of all soldiers invalided from the army are sent to the Ministry of Pensions, and in cases where men discharged in the ordinary way subsequently claim a disability pension their medical history sheets and other documents are always obtained by the Ministry of Pensions from the Record Office.

Rehearing of Pensions Appeals.

Colonel ASHLEY asked the Pensions Minister whether, in view of the fact that a statutory right to pension had now been conceded and new tribunals unconnected with the Ministry of Pensions were being set up to deal with claims, an opportunity would be given for the rehearing of appeals disallowed by the appeal tribunals under the jurisdiction of the Ministry, as in many cases great hardship had resulted from the decision of the tribunal in question.—Sir J. CRAIG (Parliamentary Secretary to the Ministry of Pensions) replied: The class of case to which my honourable and gallant friend refers is specifically excluded from the right of further appeal by the War Pensions (Administrative Provisions) Act, 1919, and the reasons for its exclusion were explained in the debate which preceded the passing of the Act. The appeal tribunals set up under the Ministry were not subjected to any interference by this Department and only differed from the present tribunals in that their decisions were not legally binding on the Minister, although almost invariably accepted by him.

Appointments

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

ANDREWS, J. A., has been appointed Medical Officer for the Bovey Tracey district by the Newton Abbot Board of Guardians.

FORSYTH, J. A. CAIRNS, M.Sc., F.R.C.S., Surgeon to Out-patients, Royal Waterloo Hospital for Children and Women.

LUCE, Sir R., K.C.M.G., C.B., to be one of the Medical Referees under the Workmen's Compensation Act, 1906, for County Court Circuit No. 19.

MALLAM, W. A., M.R.C.S., L.R.C.P. Lond., Medical Director of the International Hospital, Naples, Italy,

TAPPER, K., Assistant Medical Officer for the County of Dorset.

WOOD, W. V., M.R.C.S., L.R.C.P., Medical Officer for the Yatton (Somerset) District.

WOODFORDE, A. W. G., M.B., B.S. Lond., Honorary Registrar to the Samaritan Hospital for Women, Liverpool.

Great Northern Central Hospital: GRAHAM, G., M.D., M.R.C.P. Lond., and ADEY, W. J., Physicians with charge of Out-patients; SOUTER, M. J. K., L.D.S. R.C.S., Assistant to the Dental Surgeon.

St. Thomas's Hospital: CARDELL, J. D. M., M.R.C.S., L.R.C.P. Lond., POTTER, A. F., M.R.C.S., L.R.C.P., STORMER, H. G., M.R.C.S., L.R.C.P., BILLINGTON, C. M., M.R.C.S., L.R.C.P., COOKE, R. C., M.R.C.S., L.R.C.P., HALE, J., M.R.C.S., L.R.C.P., SPENCE, D. B., M.R.C.S., L.R.C.P., WOOD, F. G., M.R.C.S., L.R.C.P., Casualty Officers and Resident Anæsthetists; DAWSON, W. S., M.A., M.B., B.Ch. Oxon, M.R.C.S., L.R.C.P., WHITCOMBE, R. C. P., B.A. Cantab., M.R.C.S., L.R.C.P., WARE, S. A. T., M.R.C.S., L.R.C.P., PROCTER, R. A. W., M.R.C.S., L.R.C.P., Resident House Physicians; SMITH, J. FOREST, M.R.C.S., L.R.C.P., Resident House Physician for Children; ROBINSON, R. H. O. B., M.B., B.C. Cantab., M.R.C.S., L.R.C.P., WAYTE, J. W., M.B., B.S. Lond., M.R.C.S., L.R.C.P., PERKINS, G., M.B., B.Ch. Oxon., M.R.C.S., L.R.C.P., HUMPHREYS, R. M., M.B., B.Ch. Oxon., Resident House Surgeons; MARINER, H. I., M.R.C.S., L.R.C.P., Resident House Surgeon for Ear, Nose, and Throat; HIGGINS, L. G., M.R.C.S., L.R.C.P., House Surgeon; RICHARDSON, A. H., M.B., B.C. Cantab., F.R.C.S. Eng., GARSON, H. L., M.R.C.S., L.R.C.P., Obstetric House Physicians; WALKER, J. P. S., M.B., B.Ch. Oxon., BROCKMAN, E. P., M.R.C.S., L.R.C.P., Ophthalmic House Surgeons; CAVENAGH, J. B., M.B., B.Ch. Oxon., M.R.C.S., L.R.C.P., DOORLY, A. R. C., M.B., B.S. Lond., M.R.C.S., L.R.C.P., Clinical Assistants to Throat Department; GARDINER-HILL, H., M.B. Cantab., M.R.C.S., L.R.C.P., HALLIWELL, A. C., M.R.C.S., L.R.C.P., Clinical Assistants to the Skin Department; BRETT, P. C., M.R.C.S., L.R.C.P., SPROTT, N. A., B.A., M.B., B.Ch. Oxon., M.R.C.S., L.R.C.P., Clinical Assistants to the Ear Department; SPEAR, F. G., M.R.C.S., L.R.C.P., Clinical Assistant to the Electrical and X Ray Department.

Certifying Surgeons under the Factory and Workshop Acts: FFOULKES, M., M.R.C.S., L.R.C.P. Lond. (Abergele); WILLIAMS, O. E., M.R.C.S., L.R.C.P. Lond. (Mold); RICHARDS, W. G., M.B., Ch.B. Edin. (Llansawel).

Vacancies.

For further information refer to the advertisement columns.

Argyll and Bute District Asylum, Lochgilphead, Argyllshire.—Asst. M.O. £250.

Wakefield, West Riding County Council.—Sch. Med. Inspector. £500.
Westminster Hospital, Broad Sanctuary, S.W.—H.P.
Wigan County Borough Education Committee.—Part-time School Dentist. £150.
Wigan Infirmary.—Jun. H.S. £225.

The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Hungerford and at North Walsham.

Births, Marriages, and Deaths.

BIRTHS.

Blackstock.—On Feb. 11th, at The Elms, Eskbank, Midlothian, to Dr. and Mrs. Hall Blackstock—a daughter.

MARRIAGES.

Dunne—Henderson.—On Feb. 11th, at the Parish Church, Holy Trinity, Brompton, Major J. S. Dunne, D.S.O., R.A.M.C., to Catharine Henderson, M.B.E., only child of Admiral and Mrs. Henderson.

Keith—Mackey.—On Feb. 11th, at St. Faith's, Maidstone, William Brooks Keith, M.C., M.D., to Dora, elder daughter of Mr. and Mrs. W. J. Mackey, of The Highlands, Maidstone.

DEATHS.

Dickson.—On Feb. 11th, at Blackheath, Captain Alexander Collingwood Dickson, R.A.M.C. (retired), aged 42 years.

Murphy.—On Feb. 13th, at Military Hospital, Chisledon, of heart failure, Francis Murphy, temporary Captain, R.A.M.C.

Prior.—On the 4th Feb., at Watford, Mrs. Alice Percival Prior, widow of Richard Henry Prior, M.D., J.P., formerly of St. Albans, Herts, aged 71 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

Thursday, Feb. 26th.—Papers:—Mr. L. F. Richardson: Some Measurements of Atmospheric Turbulence (communicated by Sir Napier Shaw).—Mr. W. G. Duffield, Mr. T. H. Burnham, and Mr. A. A. Davis: The Pressure upon the Poles of Metallic Arcs, including Alloys and Composite Arcs (communicated by Prof. O. W. Richardson).—Mr. J. H. Hyde: On the Viscosities and Compressibilities of Liquids at High Pressure (communicated by Prof. J. E. Petavel).—Mr. A. Russell: The Capacity Coefficients of Spherical Conductors (communicated by Dr. C. Chree).—Mr. C. Cuthbertson and Maude Cuthbertson: On the Refraction and Dispersion of Carbon Dioxide, Carbon Monoxide, and Methane.—Mr. A. A. Griffith: The Phenomena of Rupture and Flow in Solids (communicated by Mr. G. I. Taylor).

ROYAL SOCIETY OF MEDICINE 1, Wimpole-street, W.

Tuesday, Feb. 24th.

SOCIAL EVENING: at 8.30 P.M.

Mr. C. Edward Wallis will show Some Objects of Great Historical Dental Interest, kindly lent by the Wellcome Medical Museum and Mr. Joseph Ash. Mr. Wallis will also give a twenty minutes' talk on "The History of Artificial Teeth, including the Gold Bridge Work of the Ancient Etruscans."

The Library will be open, and various objects of interest will be exhibited. Music and light refreshments. It is hoped there will be a good attendance of Fellows and their friends, who will be cordially welcomed.

MEETINGS OF SECTIONS.

Monday, Feb. 23rd.

ODONTOLOGY (Hon. Secretaries—G. Paton Pollitt, W. Kelsey Fry J. Howard Mummery): at 8 P.M.

Clinical Evening. Cases (at 7.45 P.M.).

Tuesday, Feb. 24th.

MEDICINE (Hon. Secretaries—W. Cecil Bosanquet, J. H. Thursfield): at 5.30 P.M.

Colonel Ransom Pickard and Dr. G. W. Lloyd: Early Manifestations of Scurvy.
Dr. S. Dutton: Some Deficiency Diseases and Leprosy.

Thursday, Feb. 26th.

ELECTRO-THERAPEUTICS with the RONTGEN SOCIETY and the INSTITUTION OF ELECTRICAL ENGINEERS (Hon. Secretaries of the Section—Walter J. Turrell, Stanley Melville): from 5 to 6.45 P.M.

Dr. Reginald Morton: Efficiency of High Tension Transformers.
Major C. E. S. Phillips, O.B.E.: The Problems of Fluctuating and Alternating Currents.
Mr. R. S. Wright, M.I.E.E.: High Tension Transformers.

Discussion, Exhibition of Apparatus: from 8.15 to 10 P.M.

Friday, Feb. 27th.

STUDY OF DISEASE IN CHILDREN (Hon. Secretaries—E. A. Cockayne, H. C. Cameron, C. P. Lapage): at 4.30 P.M.

Discussion:

On "The Influence of Accessory Food Factors in Infant Feeding." To be opened by Dr. Mellanby. Professor Noel Paton, Dr. C. J. Martin, Dr. E. A. Barton, Dr. Robert Hutchison, and Dr. E. Cautley will also take part.

Members who wish to take part in the Discussion are asked to send in their names to Dr. Cameron, 23, Devonshire Place, W.

Members of other Sections are cordially invited.

EPIDEMIOLOGY AND STATE MEDICINE (Hon. Secretaries—William Butler, M. Greenwood): at 8.30 P.M.

Dr. Matthew Young: An Investigation into the Periodicity of Epidemics of Whooping-cough from 1870 to 1910 by Means of the Periodogram.

Those Members of the Section who wish to attend the dinner at the Welbeck Palace Hotel, at 7 P.M., are requested to notify Dr. Major Greenwood, Lister Institute, Chelsea Gardens, S.W. 1, not later than Feb. 25th.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 23rd.—8.30 P.M., Sir Charters Symonds, K.B.E., C.B.: The Surgical Treatment of the Later Stages of Gunshot Injuries of the Chest and of Empyema (illustrated by the epidiascope).—Dr. P. M. Smith: The After-results of Certain Surgical Operations.

ILLUMINATING ENGINEERING SOCIETY, at the Royal Society of Arts, 18, John-street, Adelphi, W.C.

Tuesday, Feb. 24th.—8 P.M., Discussion on Lighting Conditions in Mines, with Special Reference to the Eyesight of Miners. Dr. T. L. Llewellyn and others will take part in the discussion.

BRITISH PSYCHOLOGICAL SOCIETY (Industrial Section), at the Examination Rooms of the Royal College of Physicians, 8-11, Queen-square, Bloomsbury, W.C.

Wednesday, Feb. 25th.—6 P.M., Dr. H. M. Vernon: The Effect of Change in Hours of Work on Output.

HUNTERIAN SOCIETY, in the Hall of the Society of Apothecaries, Water-lane, Ludgate Hill, E.C.

Wednesday, Feb. 25th.—9 P.M., Presidential Address:—Dr. W. Langdon Brown: Hunter, Gaskell, and the Evolution of the Nervous System.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East.

Thursday, Feb. 26th.—5 P.M., Milroy Lectures:—Dr. A. Castellani, C.M.G.: The Higher Fungi in Relation to Human Pathology. (Lecture I.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Monday, Feb. 23rd.—5 P.M., Arris and Gale Lectures:—Prof. G. E. Smith: The Evolution of the Cerebellum. II., The Mammalian Cerebellum.

UNIVERSITY OF LONDON.

Advanced Lectures in Physiology to Students of the University and others interested in the subject.

A Course of Eight Lectures on Physiologically Balanced Solutions will be given by Dr. W. L. Symes in the Physiological Laboratory of the University, South Kensington, S.W.:—

Tuesday, Feb. 24th.—5 P.M., Lecture V.

A Course of Eight Lectures on the Reaction of the Blood and Acidosis will be given by Dr. J. W. Trevan, at St. Bartholomew's Hospital, West Smithfield, E.C.:—

Wednesday, Feb. 25th.—4.30 P.M., Lecture V.

A Course of Eight Lectures on the Regulation of Respiration will be given by Dr. M. S. Pembrey and Mr. J. H. Ryffel at Guy's Hospital, Borough, S.E.:—

Thursday, Feb. 26th.—4.30 P.M., Lecture VIII.

LONDON HOSPITAL MEDICAL COLLEGE (UNIVERSITY OF LONDON), Mile End, E.

A Course of Instruction on the Diseases of Children, open to Post-Graduates and to Students of the Hospital. (The lectures will be illustrated by lantern slides.)

Monday, Feb. 23rd.—9.15 A.M., Lecture VII.:—Dr. Thompson: Organic and Functional Nervous Diseases, Meningitis and Mental Deficiency. (At the Anatomical Theatre.)

Wednesday.—10 A.M., Clinical Demonstration:—Dr. Miller. (At the Children's Out-patient Department.)

Saturday.—10.15 A.M., Lecture VIII., Dr. Hutchison: General Diseases. (At the Anatomical Theatre.)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).

A Post-Graduate Course of Lectures on Syphilis is being given by various members of the staff of King's College Hospital during the present year.

Friday, Feb. 27th.—9.15 P.M., Prof. Sir StClair Thomson: Syphilis of the Throat, Larynx, &c.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, W.

Monday, Feb. 23rd.—11 A.M., Out-patients: Dr. Goodall. 2 P.M., In-patients: Dr. Moon.

Tuesday.—2 P.M., Out-patients: Dr. R. Wells. 3 P.M., In-patients: Dr. Gibbes.

Wednesday.—2 P.M., Out-patients: Dr. Moon. 5.30 P.M., Lecture:—Dr. Hamill: Heart Failure.

Thursday.—10 A.M., In-patients: Dr. Hamill: 2 P.M., Out-patients: Dr. Price.

Friday.—2 P.M., Out-patients: Dr. Gibbes. 2.30 P.M., In-patients: Dr. Wells.

Saturday.—10.30 A.M., In-patients: Dr. Hamill.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.

Special Course of Lectures and Demonstrations on Tuberculosis for Medical Men and Women qualifying to become Tuberculosis Officers, General Practitioners, and others. Bacteriological Demonstrations will be given in the Laboratories of the Institute, and visits arranged to Sanatoriums, Tuberculosis Dispensaries, &c.

Thursday, Feb. 26th.—5 P.M., Lecture VII.:—Dr. W. E. C. Dickson: Some Pathological Aspects of Tuberculosis.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Tuesday, Feb. 24th.—2 P.M., Demonstration:—Dr. R. M. Murray: Cases of Pneumonia. 4.30 P.M., Lecture:—Dr. R. M. Murray: The Complications of Pneumonia.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, Feb. 23rd.—2–3.30 P.M., Out-patient Clinic: Dr. Collier. 3.30 P.M., Mr. Paton: Ophthalmoplegia.

Tuesday, Feb. 24th.—2–3.30 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Ward Cases: Dr. Risien Russell.

Wednesday, Feb. 25th.—2 P.M., Mr. Sargent: Surgical Treatment of Spinal Caries. 3.30 P.M., Dr. James Taylor: Epilepsy.

Thursday, Feb. 26th.—2–3.30 P.M., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 P.M., Dr. Farquhar Buzzard: Intracranial Tumours. II.

Friday, Feb. 27th.—2–3.30 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Ward Cases: Dr. Tooth.

Saturday, Feb. 28th.—9 A.M., Surgical Operations.

Fee for Post-Graduate Course £7 7s. C. M. HINDS HOWELL, Dean.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Saturday, Feb. 21st.—10 A.M, Dr. A. Saunders: Medical Diseases of Children.

Monday, Feb. 23rd.—5 P.M., Dr. Beddard: Practical Medicine. (Lecture III.)

Tuesday.—5 P.M., Mr. Page: Spinal Anæsthesia.

Wednesday.—5 P.M., Mr. Steadman: Dental Sepsis—Children, its Causes, Consequence, and Treatment.

Thursday.—5 P.M., Dr. G. Stewart: Treatment of Diseases of the Nervous System of Syphilitic Origin.

Friday.—5 P.M., Special Lecture:—Dr. J. S. Risien Russell: A Diagnosis of Affections of the Cerebellum.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton, S.W.

Wednesday, Feb. 25th.—4.30 P.M., Dr. Beaumont: The Influence of War on Respiratory Disorders.

MEDICO-PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND, 11, Chandos-street, W.

Tuesday, Feb. 24th.—2.45 P.M., Paper:—Dr. R. H. Steen: Chronic Hallucinatory Psychosis.

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE POST-GRADUATE DEMONSTRATIONS, at the Sheffield Royal Hospital.

Monday, Feb. 23rd.—3.30 P.M., Dr. Nutt: X Ray Examination of Gullet and Stomach.

Tuesday.—4 P.M., Dr. Hay: Disorders of Motility of Eye.

Wednesday.—3.30 P.M., Dr. Wilkinson: Dysphagia.

Thursday.—3.30 P.M., Dr. Skinner: Eczema.

Friday.—4 P.M., Dr. Hay: Diseases of the Optic Nerve.

UNIVERSITY OF BIRMINGHAM—FACULTY OF MEDICINE, in the Anatomical Theatre, Edmund-street, Birmingham.

Post-Graduate Course of Lectures on Venereal Disease:—

Wednesday, Feb. 25th.—4.15 P.M., Mr. B. Whitehouse: Syphilis in Relation to Pregnancy.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, Feb. 24th.—4.30 P.M., Lecture:—Dr. E. B. Leech: The Use of Pancreatic Preparations for Digestive Disorders.

SALFORD ROYAL HOSPITAL AND ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

Thursday, Feb. 26th.—4.30 P.M., Lecture:—Dr. Ward: Bronchial Affections of Childhood. (At Ancoats Hospital.)

Notes, Short Comments, and Answers to Correspondents.

THE ROYAL EDINBURGH ASYLUM AND THE UNIVERSITY CHAIR OF PSYCHIATRY.[1]

BY PROFESSOR GEORGE ROBERTSON,
M.D. EDIN., F.R.C.P. EDIN.,
PHYSICIAN-SUPERINTENDENT OF THE ROYAL ASYLUM, MORNINGSIDE.

THE idea of founding this chair was first brought up early in the nineteenth century by Sir Alexander Morison, but Professor Hope, the chemist, whose opinions carried great weight, was averse to the innovation. Sir Alexander Morison had cited as a precedent for his proposal the comparatively recent establishment of a Chair of Agriculture. Professor Hope replied that the parallel did not hold good. He quite approved, he said, of a Chair of Agriculture, but not one of ploughing, nor, for that matter, of pleurisy; and he evidently classed mental diseases in much the same category. He even expressed the fear, if the thin end of the wedge were thus inserted, that some dropsical old gentleman might leave a sum of money to endow a chair of dropsy or of liver disease, and this argument, which may seem puerile now, convinced his colleagues and blocked the proposal. It has been revived from time to time, but it took nearly a hundred years to get the principle accepted and the necessary action taken.

The managers of the Royal Asylum have now, at a critical period of development in our history, conferred a signal benefit on the University and the Medical School by providing the necessary fund to endow a Chair of Psychiatry. It has therefore occurred to me, in grateful recognition of their public-spirited action, that an appropriate subject for my inaugural address would be an account of the events that led up to the founding of the Royal Asylum. The story forms an interesting romance which it would be a pity to forget, and it also supplies us incidentally with psychological instruction.

The Founder of the Royal Edinburgh Asylum.

The founder of the Royal Edinburgh Asylum was Dr. Andrew Duncan, senior, President of the Royal College of Physicians. Dr. Andrew Duncan was one of the most useful citizens Edinburgh ever possessed. He was full of zeal for his profession, for works of medical benevolence, and for social well-doing generally. It is hard to believe that what he accomplished in his lifetime was the work of one man, and Lord Cockburn was probably in earnest when he wrote that he was the promoter and President of more clubs and societies than perhaps any man in the world. He was the founder of three useful and successful Royal corporations, the Royal Asylum, the Royal Public Dispensary, and the Royal Caledonian Horticultural Society. He also founded the Æsculapian Club, the Harveian Society, and the Medico-Chirurgical Society. He edited for 30 years the "Medical Commentaries" and the "Annals of Medicine," which still exist as the *Edinburgh Medical Journal*. He held two professorships at the University, he served two terms of office as President of the Royal College of Physicians, and he was first physician to the King in Scotland. He founded a sea-bathing club and a gymnastic club, and it is recorded that he even climbed to the top of Arthur's Seat every May-day morning till he was 83 years of age. It is not surprising that so remarkable a citizen should have received the honour of the freedom of the city. Not only do we know that Dr. Duncan was the founder of the Royal Asylum, but we also know how the idea of the need for providing a mental hospital for Edinburgh originated in his mind.

Robert Fergusson.

When a young man, 30 years old, he was called on to treat the poet, Robert Fergusson. Dr. Duncan found Fergusson in a state of furious insanity, living in the home of his mother, an elderly widow in straitened circumstances. Her feeble state and the situation of her house made it impossible to treat the patient or to secure his safety while he remained at home. After fruitless efforts to have him provided for in a more suitable place, he was removed to the City Bedlam. This was situated within the triangular block of buildings behind Teviot-place, and it probably stood exactly opposite to, and within a stone's-throw of, the main entrance of the new University buildings. In one of the cells in this bedlam of the Charity Workhouse the poet Fergusson was therefore confined. The floor of the cell consisted of stone flags, the only furniture was a bed of loose straw, and the opening admitting air and light to it was probably unglazed. After some months the symptoms of morbid elation or mania passed off and despondency or melancholia of a religious kind took their place, this being the typical course of events in the form of disorder known as "manio-depressive insanity." The patient grew thin, became exhausted, and finally died on Oct. 15th, 1774, about ten months after his admission. In the old minute-book recording the deaths the chilling record stands thus: "Mr. Fergusson, in the cels."

Robert Fergusson was a genius. He was one of the three finest poets in the vernacular that Scotland has ever produced. Henley writes: "There can be no question but in his death at four-and-twenty a great loss was inflicted on Scottish literature." In a state of mild mania or elation characterised by a rapid flow of uncontrolled ideas he must have been a supremely brilliant and fascinating, if erratic personality; and in his final phase of religious despondency or melancholia, a most pathetic one. It is therefore not surprising that the deplorable surroundings for treating the malady of one so highly gifted and sensitive made a deep impression on his young physician. He wrote to the Lord Provost: "It is impossible to conceive a more interesting object of charity than the man of genius, when a pauper lunatic." Nothing practical that we know of was done in connexion with this matter between 1774, when Fergusson died, and 1790 when Dr. Duncan was elected president of the Royal College of Physicians, and announced his scheme for providing a mental hospital for Edinburgh.

Awakening Humanity: John Howard.

During this interval of 16 years, the world was not standing still. Some of the most remarkable events in history were taking place, which altered for ever the mental outlook of mankind. A new day was dawning in which a more even sense of justice, a stronger instinct of freedom, and a truer realisation of the brotherhood of man were coming into being. The year after Fergusson died (1775), our American colonists fired the first shots in their struggle for independence, which "shook the world." The year before Dr. Duncan was elected president (1789), the mob of Paris stormed the Bastille, accomplishing one of the memorable events in the history of the world. At this time (1787) Wilberforce formed the Association for the Abolition of the Slave Trade. Not only to the negro in slavery, but to the white man in captivity was sympathy extended, for, by a curious circumstance, it was during this very period of 16 years, between 1774 and 1790, that John Howard, the prison reformer, laboured. When a young man, aged 29, he had been captured at sea, and made a prisoner of war in France. He thus knew from personal experience the horrors of prison life. In 1773 he was appointed sheriff of Bedfordshire, and it was part of his duties to inspect the prisons and prisoners within his jurisdiction. Their misery and neglected condition at once aroused his sympathy, for they recalled vivid recollections of his own painful experience 18 years previously, when a prisoner of war. Such was the volume of emotion thus aroused, that thereafter he devoted the remaining 16 years of his life to exploring the prison world of Europe and ameliorating the lot of the prisoner. This investigation is related to the care of the insane, not only because the insane were treated like prisoners in those days, but also because Howard found that prisons were overcrowded, owing to the presence of insane persons detained in prison because there was nowhere else to keep them in safety. Before the end of his life he had another reason for interesting himself in the care of the insane, for his only son became afflicted in mind and died insane.

It is well known that Howard's work "On the State of Prisons in Europe" attracted universal attention, but it is not so well known that his reports on hospitals and the care of the insane were also received with great respect. In proof of the influence exerted by him on the treatment of the insane stronger evidence cannot be advanced than this: that Esquirol, when describing the great reform which is the glory of his teacher, Pinel—namely the introduction of the humane system of treatment—frankly points out that Howard's work led up to it. Increased solicitude for the care of the insane was therefore the natural result of the history of the time. It is not possible to explain otherwise how movements for their amelioration should have been started simultaneously by persons acting quite independently in so many different parts of Europe—Andrew Duncan at Edinburgh in 1790; Joseph Paquin at the Chambery Asylum in Savoy in 1791; William Tuke at York in 1792; Philippe Pinel at the Bicêtre in Paris in 1793; and Vincenso Chiarugi at the San Bonifazio Asylum in Florence in the year 1793.

There were two other factors that probably determined Dr. Andrew Duncan to initiate his good work. The first in time and importance, I believe, to have been the visit of the poet Robert Burns to the city of Edinburgh in the winter of 1786–87. The second was the attention directed to the malady by the insanity of King George III. Burns had a great admiration for the work of the poet Fergusson, which served as a model for his own. Shortly after his arrival in Edinburgh he made inquiries regarding the burial place of Fergusson, who had been interred in a pauper's grave in the Cannongate Churchyard. Burns found the grave unmarked and neglected, and obtained permission from the Kirk session of the Cannongate to erect a tombstone to the poet's memory. It is possible that he obtained his information egarding the burial place from Fergusson's physician, whom we know to have been one of those who was keenly interested in him during his last illness. Duncan was also sufficiently interested in Burns to subscribe for a copy of the Edinburgh edition of his poems.

---

[1] An abstract of an inaugural address delivered on Jan. 22nd, 1920.

It appears to be a not unreasonable surmise that the interest shown by Burns in the poet Fergusson attracted attention to him and was the means of reviving in Dr. Duncan's mind his melancholy end, and with it the absence of adequate means of treating mental disease in Edinburgh. This revival 12 or 13 years after of a deep impression made during youth, with the resulting emotional energy that such an occurrence sets free, is exactly comparable to what happened in the case of John Howard. As already stated, Howard's interest in prisons was awakened after a period of ormancy lasting some 17 or 18 years, since the time he himself had been a prisoner of war. These two instances illustrate that a concrete experience, especially if received in impressionable youth and accompanied by strong emotion, may be in after life the irresistible motive power of high ideals and of conduct. The other event that probably influenced Dr. Duncan was the insanity of King George III. There is no doubt that the attacks of insanity to which the King was subject, directed attention to this malady in Great Britain, which it would not otherwise have received.

The Foundation.

The opportunity for which Dr. Andrew Duncan, now professor of physiology in the University, had been waiting came at last when he was elected President of the Royal College of Physicians on Dec. 2nd, 1790. He lost no time in carrying into effect the project on which he had set his heart. On the day following his election to the post of President, in virtue of his office as representative of the College of Physicians on the board of managers, he revisited the City Charity Workhouse and inspected the cell of its Bedlam in which Fergusson had died 16 years before. He immediately brought the matter before his council, and referred to it at the first meeting of the College, held in February, 1791. A committee was appointed, which reported in May that the establishment of an asylum in the neighbourhood would be of the utmost advantage, and made proposals as to the question of funds and the appointment of trustees. In August the report was finally approved, and the President was instructed to approach the Lord Provost on the subject. On Feb. 7th, 1792, it was reported that all the gentlemen proposed as trustees had accepted nominations, and the College then subscribed a sum of £25 towards the scheme. Three weeks later, on the suggestion of the College of Physicians, circulars were issued by the Lord Provost and other trustees and distributed to the public, describing the objects of the proposal and requesting subscriptions. On this date, therefore, Feb. 26th, 1792, the whole scheme for providing an asylum and suitable treatment for the insane in Edinburgh was publicly launched. By a strange coincidence only six days later, March 3rd, 1792, William Tuke at the close of the quarterly meeting of the Society of Friends, held at York, proposed the establishment of a retired habitation for deranged members of the Society, afterwards to become so well known as "The Retreat."

Owing to a variety of causes, of which the Napoleonic wars and the disturbed state of the country were the most important, subscriptions did not come in freely for 14 years, in spite of the nest-egg provided by the Royal College of Physicians. This was not surprising, as during this period there was a complete interruption of charitable work all over the kingdom, as there was of charitable legislations as well. A sum of £2000 was, however, given towards the scheme on July 23rd, 1806, by the Crown (46 George III., c. 156) from funds obtained by the sale of the highland estates forfeited in the Rebellion of 1745, a most unexpected source from which to obtain money for such an object. This sum enabled the trustees to purchase a site for the new asylum in the adjacent village of Morningside, now absorbed by the city. Generous contributions also resulted from a new address to the public composed by the Very Rev. Dr. Baird, Principal of the University. The foundation-stone of the asylum was ultimately laid by Lord Provost Coulter on June 8th, 1809, and the first patient was admitted on July 19th, 1813.

By the establishment of a mental hospital in one of the suburbs of Edinburgh, the first requisite for clinical instruction in mental diseases was thus provided for. This was one of the objects anticipated by its founder, and held forth by him among the other claims which it had upon the liberality of the public. This object was still further emphasised by a medical committee over which Dr. David Maclagan, the father of the late Sir Douglas Maclagan, acted as convenor. In their report, dated Dec. 23rd, 1835, it is stated that under judicious regulations the institution may be run most usefully as a school of instruction in the observation and treatment of mental diseases. Thirteen months afterwards the managers resolved to erect an additional building for the reception of parochial patients, and this was opened in 1841. It is now known as the West House and it is here that clinical instruction has been given regularly since the year 1853.

The Chair of Psychiatry.

It is evident that the board of managers have always taken a serious view of their responsibility for the provision of facilities for clinical instruction. There is, in consequence of this attitude, no mental hospital where the tradition of teaching exists to a stronger extent than in the Royal Asylum at Morningside, nor any medical school that has been better served than that of Edinburgh. It is only in keeping with this high tradition and to further its objects that the board of managers, conceiving the time to be ripe, have finally thought it to be their duty to endow a Chair of Psychiatry in the University of Edinburgh.

MENTAL DEFECTS AND THEIR DIAGNOSIS.

IN the course of two lectures delivered under the auspices of the Central Association for the Care of the Mentally Defective at the Fabian Hall, Tothill-street, Westminster, London, S.W., on Jan. 20th and 27th, Dr. Letitia Fairfield dealt with the types and varieties of mental deficiency, with their differential diagnosis from blindness and deafness. She said that the stigmata of degeneration, such as a sharply incurved little finger, a marked epicanthus or a high palate, were frequently found in normal intelligent persons, but the occurrence of two or more of these signs commonly indicated mental defects. The difference between the normal and abnormal child did not lie only in the structure of the muscles and bones of the solid parts of the face, or in the pose and walk; much of the characteristic appearance of an individual depended on the control of the muscles by the mind, and it was here that a contrast was often manifest. After describing the typical appearance of the microcephalic and hydrocephalic, and other abnormal types, the lecturer passed on to the mental characteristics caused by endocrine deficiencies; and lastly to the puzzling condition caused by such defects in the senses leading to dullness, often mistaken for mental defects.

Differential diagnosis.—Certain abnormalities in a child might produce symptoms that would suggest lack of intelligence when the trouble was really a sense-deficiency of hearing or vision. The diagnosis was very important and should be made in the home if possible. In the days before school inspection these defects were common, but in recent years the lecturer had had to deal with only one case, that of a girl who was thought to be mentally deficient but who really was suffering from deafness. These cases could only be differentiated by keen observation. A baby in the cradle would not be likely to indicate lack of sight unless it was almost completely blind. Such complete blindness would seldom occur without an obvious defect in the eye or in the presence of nystagmus; this was a most important sign to watch for. A child might respond quickly to sound but take no notice of bright light; an idiotic child was frequently blind. When testing one sense the others should be excluded. The observing mother seldom made a mistake. When the child was able to walk it should be noted whether it stumbled, whether its interest was attracted by anything pretty, whether it held a bright object close to its face. Its inability to recognise things by feel was another test. The distinction between the deaf child and the defective was often very difficult, and was a common source of error both in teachers and doctors. A child very rarely knew that it was deaf, because it had no standard of hearing, and thus could not plead deafness in its own defence. More especially was there difficulty if the deafness was partial. A clever deaf child was much more likely to be taken for a mental deficient than a stupid one. A totally deaf or stupid child would lack speech, and this would at once arouse suspicion that the child was deaf. If the child was only partially deaf and at the same time clever it would learn to speak and to use its other senses to make up for the lack of hearing. Sometimes it would unconsciously learn lip-reading. In testing hearing care should be taken not to make signs, and a noise made behind the child's back, such as clapping hands, should be performed so far away that the patient would not feel any movement of air. In testing the child by the voice the forced whisper should be used, so as to avoid giving indications to the child by the pitch of the tester's voice. The child should stand sideways to the operator, at a distance of 20 feet, and have the ear on the far side blocked. The pronunciation of 66 and 99 were good tests, but sibilants, dentals, and labials should be used in turn. In adenoid cases deafness was often intermittent, and a set test was not always reliable. Idiotic and paralysed children were often completely deaf.

GRADE "A" MILK.

THE rules governing the sale of Grade "A" (Certified) Milk are to be subject to revision after March 14th next, and new licences will be issued only when the wholesale or retail distributor complies with conditions satisfying a representative of the Ministry of Health or of the Scottish Board of Health or of specially empowered local authorities. The herd from which the milk is obtained must contain no cow, or heifer in milk or in calf, or other bovine animal, kept in contact with the herd, which has not passed specified tuberculin tests. The additional conditions are that:—

1. The milk must be cooled and bottled immediately after production for delivery to the consumer in bottles which have previously been sterilised by steam on the premises where the milk is produced.
2. Every bottle must be covered with a suitable outer cap overlapping the lip of the bottle, and this cap must bear the name and address of the producer or of the farm where it is produced, the day of production, and the words "Grade A (Certified) Milk."
3. The milk on examination at any time before delivery to the consumer must not contain *B. coli* in one-tenth c.cm. (in each of two tubes) or more than 30,000 bacteria per c.cm.
4. The milk must not be delivered to the consumer as Grade "A" (Certified) Milk more than two days after the day of production.

COSTLY DRUGS IN GERMANY.

THE following returns taken from the *Economic Review* (Feb. 11th, 1920) are of interest in connexion with Germany's dependence upon external sources of certain drug supplies:—

> A report on the chemical market in 1919 states that few markets showed such chaotic conditions, owing to the impossibility of meeting the colossal world demand for chemicals and, especially, pharmaceutical articles.
>
> The abolition of the German war-time Acts in the territory occupied by the French has resulted in an almost unlimited trade in all kinds of medicines, which hardly contributes to improve the situation. Many of the new chemical companies, whose name is legion, show a regrettable lack of expert knowledge. A large number of metal works have established "chemical sections." The extraordinary increase in prices is shown by the following figures (in marks):—

	1914.	*1917.*	*Jan., 1919.*	*July, 1919.*	*Dec., 1919.*
Quinine, hydrochloride	44	113	137	500	1200
Chloroform	1·40	5·20	6	15	30
Silver nitrate	55	145	165	450	1050
Pot. bromide (1910)	2	3·10	3·75	15	60
Menthol recryst.	28	72	160	480	1150
Resorcine (1912)	6	15·50	50	—	390
Pot. iodide	26	32·50	127	—	450

> The report refers to chemical preparations for the supply of which Germany is dependent upon foreign countries. In the middle of 1919, for example, English borax at about Mk. 6 ousted the German article at Mk. 28 from the market, but owing to the unfavourable exchange the price rose to Mk. 12–Mk. 14 at the end of 1919. (*Frankf. Ztg.*, Jan., 23.e.)

The figures, while showing clearly an enormous advance in prices, do not convey the cost by weight of the drugs quoted. The quotations, however, are evidently for 100 g. It is notable that synthetics do not figure prominently in the list.

FEES OF OUR ANCESTORS.

To the Editor of THE LANCET.

SIR,—Those who had the pleasure of listening to Sir D'Arcy Power's address on the above subject, delivered before the Royal Society of Medicine and published in THE LANCET of Feb. 7th, wished that he had not limited himself to 20 minutes; he might have extended the period to one hour without exhausting either his own repertoire or the interest of his audience.

His observations concerned chiefly payments made by civilians to their doctors. May I add a few of those made by Royal personages?

When the Court physician was a cleric it was only natural that payment should, in part at all events, take the form of presentation to a "living," and the number of livings bestowed was generally a measure of the degree of favour in which the physician stood with his Sovereign. Thus Linacre held simultaneously or in quick succession one canonry, three prebendaries, and five rectories, and Dr. Chambre, who preceded Linacre as physician to Henry VIII., not only held several livings in this country, but also an archdeaconry in Ireland, from personal service in which he was exempted on account of his attendance at Court.

Payments to non-clerical physicians and surgeons make a curious recital at the present time. William Holme, for instance, surgeon to Edward III., received permission to "have, chase, and carry away" all manner of wild beasts infesting the King's forests; while to John Middleton, physician to Richard II., were granted all fines due to the King through the escape of prisoners from York Castle, a remuneration, therefore, which would depend upon the carelessness of the governor and the cleverness of the prisoners. William Bredwardyne, surgeon to Richard II., was appointed constable of Dryslwyn Castle, in South Wales, and William Hatclife, physician to Henry VI., was appointed "Keeper of the Water of the Fosse," for which he was paid 6*d.* a day. A convenient way in which an impecunious monarch discharged his obligation was by allowing his surgeon to mint his own money, subject, doubtless, to restrictions; while a gentleman, whose name I have forgotten, was granted a manor bordering upon the South Coast upon the condition that he should accompany the King whenever the latter went to sea and support the King's head during sea sickness.

I am, Sir, yours faithfully,

S. D. CLIPPINGDALE.

Holland Park-avenue, W., Feb. 14th, 1920.

INDIAN INFANT WELFARE EXHIBITION.

THE Infant Welfare Exhibition has decided to award medals and certificates of merit for exhibits offered in the following classes:—

Class 1.—For the best model of a dwelling-house showing hygienic compared with unhygienic conditions. The models may be of any size.

Class 2.—For the best exhibit shown by any business firm in the interest of maternity and infant welfare.

Class 3.—For the best exhibit illustrating welfare work being carried on among employees.

Class 4.—For the best model outfit such as could conveniently be supplied to midwives and dais for use at childbirth, to mothers for preparation for childbirth, to mothers for use in connexion with first-aid and home nursing.

Class 5.—For articles calculated to improve the conditions of infancy and childhood.

Class 6.—For the best exhibit of snapshot sketches or cartoons of a nature calculated to increase public interest in maternity and infant welfare work or to illustrate matters relating to hygiene.

Class 7.—For the best essay on fly destruction.

Class 8.—For the best device for fly destruction. This may be any type, mechanical, medicinal, &c. The attention of commercial firms is specially drawn to this offer.

In addition, medals are offered by associations and private individuals as follows:—

1. By the Victoria Memorial Scholarship Fund for a model lecture, "How to Conduct a Confinement in a Poor Indian House," suitable for various specified audiences.
2. By the Association of Medical Women in India for the best set of simple models to be used in connexion with the teaching of midwifery.
3. By the Association for the Provision of Health and Maternity Supervisors for the best colloquial of "Talks to Mothers."
4. By the Association of University Women in India (Delhi and Punjab Branch) for the best model plans of a house suited to Indian families with different incomes.
5. For the best essay on the "History and Practice of Ayurvedic Midwifery," to be written in Hindi.
6. For a lecture in simple style on "How to Improve the Conditions of Childbirth in India according to the Shastras," to be written in English or Bengali.
7. For a model lesson showing the best food calculated to improve the condition of childbirth in a poor Indian house where vegetarianism is followed.

The above medals will only be awarded if a certain standard of excellence is reached. The essays for these competitions may be written in any language except where otherwise stated, and are open to all classes of people.

Major, R.A.M.C.—We should not be safe in making such wholesale charges against medical men without being able to give our authority.

Lettsomian Lectures

ON

TUMOURS COMPLICATING PREGNANCY, LABOUR, AND THE PUERPERIUM.

Delivered before the Medical Society of London on Feb. 2nd and 16th, and March 1st, 1920,

By HERBERT R. SPENCER, M.D., B.S. Lond., F.R.C.P. Lond.,
OBSTETRIC PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL.

LECTURE II.*

Ovarian Tumour Complicating Pregnancy, Labour, and the Puerperium.

Table D gives short particulars of all the cases I have seen except two: of these the first was a hospital patient who, although advised both before and during pregnancy to have an ovarian tumour removed, refused and was delivered without difficulty; on the third day of the puerperium the tumour (containing 31 pints of fluid) burst spontaneously, causing the death of the patient as soon as she reached the hospital.[1] The other case, the wife of a physician, had an ovarian tumour as big as a lemon. As it caused no trouble she was advised to await the occurrence of pregnancy. She had been married five years without conceiving. She became pregnant in 1918 and was delivered easily of a living child, and, as the tumour causes no inconvenience, she does not wish it to be removed just yet. In Table D, the column "Result of labour to child" gives the result of the labour preceding the ovariotomy in the patients operated on after delivery and following the ovariotomy in the patients operated on during pregnancy, as shown in brackets in the column "Date of ovariotomy."

Before proceeding to consider the question of treatment, it may be well to analyse the columns of the table.

Age of the patient.—The oldest patient was 43 (Case 30), the youngest 20 (Case 21), the average age was 30.

Number of children.—Nine of the patients were nulliparæ at the time the ovarian tumour was present. Three of these had multilocular cysts, one had a "parovarian" and an ovarian cyst, three had dermoids, two had ovarian fibroids.

The 55 patients had had 150 children, an average of nearly three, before the tumours were removed. Nine patients had had five or more children; one having had nine, and three having had ten children.

Number of abortions. — Thirty-three abortions had occurred before the ovariotomy in 48 patients; in 7 of the cases there is no record as to abortion. In Cases 29, 33, 42, and 47 abortions took place before the last child, and in Case 43 15 months before I saw the case, whereas four children had been born 14, 11, 8, and 6 years ago. Excluding these 7 cases, we find that the remaining 48 cases had 125 children and 33 abortions. We may suppose, therefore, that the 7 cases would have had about two abortions; this would give 35 abortions for the 55 cases. The proportion of abortions to childbirth would thus be 35 to 150.

Number of abortions in 40 cases not operated on during pregnancy.—Thirty-two abortions occurred amongst 33 patients not operated on during pregnancy. In the remaining 7 cases there is no record of the number of abortions; but in none of the 7 cases did abortion occur in the pregnancy preceding the ovariotomy. In only five of the 33 patients did abortion occur in the pregnancy preceding the ovariotomy, and about one case (Case 28) there is some doubt, the notes not recording *when* the abortion occurred. This gives an abortion-rate of at most 5 in 40 cases. If Case 28 were included the abortion-rate would be 4 in 39 cases, or, if Case 28 did not actually abort in the pregnancy preceding the ovariotomy, the rate would be 4 in 40 cases. In 5 out of 6 cases in which both ovaries were affected abortion did not occur; in the sixth case (Case 30) it is doubtful.

Number of abortions in 15 cases operated on during pregnancy.—Four of the cases aborted. Case 19 had bilateral dermoids removed at the twelfth week; Case 40 bilateral fibroids removed at the fifth week of pregnancy. Case 43 had hæmorrhage before the operation at the thirteenth week, when a large multilocular cyst was removed; the patient passed a mole 27 days afterwards. Case 47 had an acute twist of the pedicle of a parovarian cyst with hæmorrhage into the broad ligament; the tumour was removed at the thirteenth week of pregnancy two hours after the twist occurred. In 10 of the 15 cases operated on the pregnancy continued and living children were born, one dying shortly after birth. As three of the patients were operated on at term, when the question of abortion does not arise, the true abortion-rate for patients operated on before the child is viable is in this series 4 out of 12 cases.

Nature and Condition of the Tumours.

All the tumours were benign.

Cyst-adenomatous tumours were found in 33 cases; of these 22 were multilocular (in 2 cases papillomatous) and 11 unilocular; some of the latter may originally have been multilocular. The cyst-adenomatous tumours were mostly of large size; a few were small. The three ruptured tumours (Cases 32, 39, and 54) were multilocular cysts of large size. The two papillomatous tumours (Cases 13, 49) were also multilocular. Case 36 was complicated with hydrosalpinx and Case 28 with pyosalpinx and ovarian abscess.

Dermoid tumours were found in 15 cases. They were mostly small, not more than 10 to 12 cm. in their greatest diameter, the exceptions being Case 4, which contained 3 pints of pus, Case 42 (as big as an adult head), Case 53, which measured 16 cm. in its longest diameter, and Case 44, which was as big as the pregnant uterus at the sixth month, and contained pill-like balls of fat. In two of the cases the tumours were removed on both sides and in Case 38 a dermoid had been removed from the opposite side 13 years previously. Thus one-fifth of the dermoids were bilateral.

Ovarian fibroids were found in three cases: in Case 45 the tumour was small and contained pus; in Case 37 it was calcified, weighed 1 lb. 8 oz., blocked the pelvis, and was mistaken for a uterine fibroid before the operation. It was removed immediately after Cæsarean section. In Case 40 the tumours were bilateral, the right tumour weighed 3 lb. 8 oz., and was removed with the rest of the ovary; the left, an inch in diameter, was excised and the remains of the ovary stitched up. The patient had a living child next year (see "Proc. Roy. Soc. Med.," Obs. and Gyn. Section, Vol. II., p. 231).

"*Parovarian*" *tumours* were found in 6 cases. All except Case 2, which contained 10 pints, were of small size. In Case 51 a sub-fimbrial cyst on the left side was associated with an ovarian cyst on the right. In Case 48 the cyst was complicated by an inguinal hernia, operated on through the abdominal incision. In only 1 case (the only case in which the pedicle was twisted) was the corresponding ovary removed.

Torsion of the pedicle occurred in 18 cases—12 times in cyst-adenomatous tumours, five times in dermoid tumours, and once in "parovarian" tumours.

Rupture of the tumour occurred in 3 cases: Case 32 was ruptured, probably at labour, and removed a month later; Case 39 had been tapped at a lying-in hospital to relieve pressure; the tumour was removed during labour; Case 54 was admitted during labour with much free fluid in the abdomen. The diagnosis was made of ruptured ovarian cyst; it was removed 12 hours after labour and was found to be ruptured, but held 2 gallons of bloody fluid, some of which had escaped into the peritoneum. All these tumours were very large multilocular cysts. The largest ruptured ovarian tumour I have met with contained 31 pints of fluid. It burst on the third day after an easy labour. The patient had been advised, both before and during pregnancy, to have the tumour removed, but refused. She had been progressing favourably, but became collapsed when the cyst ruptured and was removed in an ambulance to hospital, but died of syncope immediately after her admission.[2] The wall of the cyst was very thin and looked as if it had been stretched.

---

* Lecture I. was published in The Lancet of Feb. 21st, p. 411.

[1] Obstet. Soc Trans., vol. xliii., p. 224.

Suppuration of the tumour was met with in 8 cases. In all cases the suppuration occurred after delivery. In Case 1 the tumour contained 2 gallons of fœtid pus, and the patient was very emaciated and feverish. In Case 4 the patient had been delivered with forceps (the child dying on the third day) and the tumour had been tapped twice, 10 pints of pus being evacuated. In Case 7 the pedicle was twisted. In Case 8 the tumour contained 15 pints of pus. In Case 12 the child was delivered (dead) with forceps; the tumour contained 26 oz. of pus. In Case 26 the tumour was small and did not become evident till the uterus had involuted. Case 28 was complicated, with an ovarian abscess and pyosalpinx on the other side. Case 45 was a small fibroid.

Six of the suppurating tumours were cyst-adenomatous, one was a fibroid, one (Case 4) was a dermoid; the infection in this case probably was caused by the tapping. The supposed proneness of dermoids to suppurate is due to an error of observation; the liquid fat at the temperature of the body looks very like pus to the naked eye. Examination with the microscope shows its nature. The fact is that dermoids very rarely suppurate. They are, no doubt, more prone to it as a result of labour, owing to the risk of injury when they are in the pelvis. Out of 59 dermoid tumours removed I have only met with suppuration in two cases besides the case mentioned above, and in one of them the tumour communicated with the sigmoid flexure of the colon; the other was published in the Medical Society's Transactions, Vol. XVII.

SEAT AND POSITION OF THE TUMOUR.

The tumour was situated in the right ovary in 23 cases, in the left ovary in 18 cases, in both ovaries in 8 cases, in the right parovarium in 4 cases, in the left parovarium in 1 case, in the left parovarium and in the right ovary in 1 case.

Incarceration of the tumour in the pelvis were met with in 5 cases[3] (Cases 21, 23, 24, 25, 37). In Case 21, who a year previously had had a dead child delivered by forceps, the tumour could not be pushed up during labour. Ovariotomy was performed, the uterus being withdrawn from the abdomen in order to permit extraction and removal of the tumour; the forceps was then applied while the uterus was outside the abdomen, and a living girl delivered who was quite well 21 years later; the mother had had nine children since the ovariotomy, and was also in good health. In Case 23 the tumour was pushed up during labour, the child delivered alive by forceps, and the tumour removed seven months later. The tumour had been present at the first labour and the first two children had been stillborn. In Case 24 the tumour, incarcerated in the pelvis at 4½ months, was pushed up and a living child was born normally at term; the tumour was removed a fortnight after delivery. After the tumour had been pushed up it occupied a position in the loin, and at term closely resembled a hydronephrosis, and might easily have been overlooked. A photograph taken at term shows little evidence of the tumour, and emphasises the importance of examination of the lumbar regions during pregnancy. In Case 25 the tumour was removed at the eighteenth week of pregnancy, and a living child was born at term. In Case 37, in which the tumour was mistaken for a *uterine* fibroid, Cæsarean section was performed, with a successful result to the mother and child.

These five cases, of which four were dermoids, show the value of treating the obstructing tumour either by pushing it up out of the pelvis or removing it by operation. The danger of delivering the child while an ovarian tumour is in the pelvis is illustrated by a specimen exhibited before the Obstetrical Society in 1898, which was ruptured during version after an attempt at delivery by forceps, with a fatal result to the mother.[4] During the course of labour the reposition of the tumour is facilitated by putting the patient in the Trendelenburg position under chloroform anæsthesia (Bossi),[5] a procedure which should always be tried before resorting to abdominal section.

If it is found to be impossible to push up the tumour, the uterus should be withdrawn from the abdomen through a 6-inch incision, which is quite long enough if the uterus be brought out cornerwise. If the child be in good condition the tumours may be removed, and the child delivered by forceps; but, if the child's heart-sounds are slowed or weak, the child should be delivered as soon as the tumour has been pulled out of the pelvis and before it is removed; thus the child will be spared some minutes of anæsthesia. It is of great importance that the cervical canal should be dilated before operation for the removal of the tumour, otherwise it may be necessary, after removing the tumour, to close the abdomen, which is done with difficulty, owing to the tension of the abdominal wall. In delivering the child at the end of the first stage it is not necessary to replace the uterus in the abdomen; the forceps may be applied (if possible, by a second operator), while the uterus lies on the abdominal wall (Case 21). If the cervical canal is not dilated the tumour should be pushed up with the patient in the Trendelenburg position, and the tumour removed at a later stage of labour or after delivery.

ADHESIONS OF THE TUMOUR.

Adhesions were found in 26 cases. The adhesions were all around the tumour in 4, to the abdominal wall in 14, to the omentum in 13, to intestine in 7, to the pelvis in 5, to the broad ligament in 4, to the uterus in 3, to the bladder in 2 cases. All the suppurating cases were adherent. Six of the 18 tumours with twisted pedicle had adhesions. Case 10 had a large cyst (8½ pints); Case 16 had been tapped; Case 21 had been delivered of a dead child, and the tumour was probably bruised. Cases 27 and 30 also had large cysts, while in Case 31 the tumour was as big as a coconut. In Cases 32 and 39 the cyst was ruptured. Case 44 had a large dermoid. Dermoid tumours, with pedicles not twisted, were free from adhesions except in two cases (21, 44).

GROWTH OF THE TUMOUR DURING PREGNANCY OR PUERPERIUM.

There does not appear to be any evidence in these cases of specially rapid growth of the tumour during pregnancy. Fifteen of the tumours were dermoids, which usually grow slowly and do not attain a size which enables the growth to be easily observed, at least by the patient. In Case 19 the left-side dermoid grew in three months from the (estimated) size of a hen's egg to the size of 8·5 × 7·5 × 6 cm.; in Case 53, the dermoid tumour at the third month of pregnancy of the size of a hen's egg measured 16 × 10 × 8·7 cm. nine months later. It must be remembered that the growth of ovarian tumours, apart from pregnancy, is often rapid. In Case 54 the growth was sudden and rapid, and the cyst ruptured during labour; it contained 2 gallons of bloody fluid, and was removed 12 hours after delivery. In Case 39 the tumour grew so fast that it had been tapped in a lying-in hospital to relieve pressure. These cases of rapid growth are, however, exceptional, and, on the whole, it appears that pregnancy exercises no special influence in increasing the rate of growth, the evidence pointing usually in the opposite direction.

In the puerperium there seems to be a greater tendency to a rapid growth. Case 7 is especially interesting from the fact that the tumour *diminished* greatly during ten weeks' observation in the hospital; the patient was also suffering from pleural effusion of tuberculous origin. A large suppurating ovarian cyst, extending high up into the abdomen, gradually got smaller, until, at the time of its removal, it was of the size of a fist. At the operation adhesions to the omentum, abdominal wall, and intestines were found to encapsule the tumour, and no doubt the vessels in these adhesions had absorbed some of the fluid in the cyst, thus leading to the remarkable reduction in size. The patient recovered well from the operation, and also eventually from the pulmonary phthisis; she was examined by me and found to be in fairly good health 27 years later.

---

[2] Ibid.

[3] The first 4 cases have been published in Obstet. Soc. Trans., vol. xl., pp. 14, 22, 259, 329, the fifth in Proc. Roy. Soc. Med., Obstet. and Gyn. Section, vol. ii., p. 232.

RESULT OF THE OVARIOTOMIES.

Fifty-five ovariotomies were performed, of which one patient died (Case 14); the tumour was a dermoid. The patient had been delivered eight months before the operation, and had noticed abdominal pain five months after the confinement. There were no adhesions. The pedicle was not twisted at the time of the operation, but the Fallopian tube was almost divided, possibly as the result of a twist which had become undone. After the operation intestinal obstruction was caused by the adhesion of a coil of small intestine to the stump of the ovariotomy pedicle. The abdomen was opened and the coil separated, but the patient succumbed.

Result of the 15 ovariotomies performed during pregnancy.—Twelve of the cases were operated on in the first half of pregnancy—viz., at the 14th, 11th, 11th, 12th, 18th, 15th, 18th, 5th, 10th, 13th, 13th, 11th week. Cases 21[6] and 39[7] were operated on during labour; Case 37[8] immediately after Cæsarean section at term. In Cases 15 and 18 labour was induced on account of contracted pelvis. All the mothers recovered. The children (in Case 3 twins) were born alive in 11 cases, but in Case 33 the child died soon after birth; four patients aborted; thus, in 5 out of 15 cases the child was lost.

Result in four other cases seen during pregnancy, operated on after delivery.—Case 2 was seen in labour; a unilocular cyst containing 10 pints was present. The patient was delivered with forceps and made a good recovery; the tumour was removed eight months later. In Case 23 the tumour was incarcerated in the pelvis during labour, the cord prolapsed, the fœtal pulse-rate was 30; the tumour was pushed up out of the pelvis, and the child delivered alive with forceps. The tumour was removed eight months later.[9] In Case 24 the tumour was incarcerated in the pelvis and was pushed up into the abdomen at four and a half months; during the second half of the pregnancy the tumour caused no trouble. A living child was born at term and the tumour was removed 15 days later.[10] Of Case 54 the particulars have been given under the heading "Rupture of the Tumour." In these 4 cases the mothers recovered and the children survived. Thus, of the 19 cases seen by the author during pregnancy all the mothers recovered; and in 15 the children were born alive and in 14 survived.

Result of the pregnancies in the 40 cases not operated on during pregnancy.—All the mothers recovered from the labour or abortion. In 29 cases (out of 37 in which the fate of the child is given) the child was born alive; in 4 cases the child died as a result of difficult delivery by forceps or version (Cases 4, 9, 12, 50). In 4 (possibly in 5) out of the 40 cases abortion occurred (Cases 20, 36, 45, 51). The mortality rate for the children is 8 out of 37.

THE OVARIOTOMY.

The ovariotomy incision was made in or near the middle line, usually through the inner edge of the left rectus muscle. In Cases 46 and 51 the transverse Pfannenstiel incision was made: this incision lessens the exposure of the intestine and the risk of hernia subsequently, but may entail more manipulation; it is only exceptionally suitable for cases operated on during pregnancy. Silk was used exclusively for ligatures and buried sutures. Drainage was employed in three cases (Cases 10, 26, 30). The pedicle was tied with interlocking silk ligatures and stitched over with fine silk. In the later cases isolated ligatures were also placed on the ovarian artery, as first practised by Burd in 1846.[11] The advisability of this practice is shown by Laroyenne's case,[12] in which a patient died in the second month of pregnancy from hæmorrhage from slipping of the ordinary ligature applied at an ovariotomy three months previously; at the autopsy the two ends of the artery were found gaping, the growing uterus having displaced the ligature by stretching the broad ligament. Fehling[13] also lost a patient from the same cause: the lower pains, which began on the day following an abdominal ovariotomy near term, after two hours caused the ligature to slip and led to intraperitoneal hæmorrhage, for which the abdomen was opened and the pedicle again tied, but too late to save the patient.

ÆTIOLOGY.

The question of the influence of pregnancy in causing malignant changes in ovarian tumours has been discussed by Sir John Williams in his Cavendish Lecture. He showed that there was no evidence of such influence. In support of this opinion is the fact that malignant ovarian tumours are rarely found in pregnancy; in my 55 cases there was not an instance, whereas, apart from pregnancy, malignancy is met with in more than 20 per cent. of ovarian tumours. It is noteworthy that in advanced age, in women over 70 years of age, malignant ovarian tumours are also rare. The cause of this rarity cannot at present be stated.

Sir John Williams also discussed the influence of pregnancy and sterility in the causation of ovarian tumours, and came to the conclusion that sterility favours their production. The question is admittedly difficult to decide from consideration of the material available. In comparing Spencer Wells's figures of ovariotomy with the figures of the 1891 Census Report, Sir John Williams assumes that the married women were mothers and the single not mothers, while pointing out that the assumption may not be quite accurate. As married women who are childless are much commoner than single women who are mothers, I think his conclusion as to the effect of sterility in causing ovarian tumours may not be justified.

The only evidence I can offer on this interesting subject is too small to be of much value. Of 8 cases of ovariotomy which I have performed on women over 70 years of age, 7 were married and had been pregnant, and 1 was a virgin. The Registrar-General's Report for 1891 shows the proportion of married to single, in those over 65, to be about 89 to 11, and, if we allow one childless marriage in ten, the proportion of pregnant women to sterile would correspond so closely with the proportion in my cases as to suggest that sterility has not the influence which Sir John Williams's statistical investigations of Spencer Wells's cases would seem to show. But I think the question cannot be answered until we know the frequency of ovarian tumours in large numbers of virgins.

SYMPTOMS.

Many patients go through pregnancy without any symptoms arising from the presence of an ovarian tumour if it is small and does not block the pelvis or become twisted or inflamed. The only way in which such tumours can be diagnosed is by routine examination of the abdomen and pelvis during pregnancy, which ought to be carried out in every case. In advanced pregnancy it is important to examine the lumbar regions, as small tumours may easily escape notice or may be mistaken for renal tumours.

Tumours which are large give rise to feelings of weight and pressure. When the tumour becomes inflamed or strangulated by twisting of its pedicle the

N.B.—In Cases 1, 7, 8, 9, 11, 12 the mother's recovery (R) after labour was complicated—in Cases 1 and 8 by high fever and extreme maciation, in Case 7 by pain after the first month; in Case 9 the mother was constantly ill after labour, and the child (cross birth, ersion) died 32 hours after; in Case 11 the mother had fever and a rigor, with peritonitis; and in Case 12 had fever and was bedridden, nable even to move her legs for four weeks. In Case 33 the child was born alive but soon died, and in Case 40 the mother recovered nd subsequently had a living child in September, 1907.

ymptoms are acute and may closely simulate strangu-ation or necrobiosis of a fibroid, acute appendicitis, or yonephrosis. The symptoms of rupture will depend pon the nature of the contents; in some cases the ccident scarcely gives rise to any other effect than lteration in the shape of the abdomen from the peri-oneal effusion; in others shock, pain, and vomiting usue. Malignant tumours are fortunately rare; they ay cause emaciation and cachexia and are usually ainful, though in some cases there are no symptoms hich suggest malignant disease.

DIAGNOSIS.

The diagnosis of pregnancy complicated with ovarian imour is usually not difficult. In some cases of early regnancy, where the ovarian tumour is large or adherent, may be difficult to make out the shape and consist-ace of the uterus. But in all cases where menstruation delayed pregnancy should be suspected, and the olour of the vagina, the consistence of the uterus, and the appearance of the breasts should be investigated; the presence of morning vomiting may help in the diagnosis. In the early months the increased width of the uterus may be made out by examining the patient bimanually in the dorsal position with the fore and middle fingers of the right hand on each side of the cervix. In conducting this examination the greatest gentleness should be used; any forcible pressure may easily separate the ovum, an objection which applies to the so-called "Hegar's sign." In the second half of pregnancy the "certain signs" (heart-sounds, parts or movements of the child and ballottement), the contraction of the uterus, and the breast changes, usually render the diagnosis of pregnancy easy if care is employed; but hydramnios may render the detection of the fœtus difficult even when the patient is placed in the kneeling position which, causing the fœtus to fall to the most dependent part of the abdomen, renders its detection by ballottement easier. It is important to bear in mind the softness of the supravaginal cervix—the physical condition which enables Hegar's sign to be obtained—which may cause the body to be apparently separate from the cervix and may, therefore, be mistaken for an ovarian tumour. Occasionally a lop-sided pregnant uterus is met with, which I have known taken for an extra-uterine tumour. If the uterus is very thin-walled—and sometimes it feels as thin as an ovarian cyst—the body, or a bulging portion of it, may be mistaken for an ovarian cyst if careless examination is made. Error is avoided by careful bimanual examination in the dorsal position, when under gentle manipulation the uterus will be felt to contract, to become one with the cervix and regular in shape.

In some cases of ectopic pregnancy a doubt may exist as to whether the enlarged uterus is pregnant or not and the tubal swelling is a mole, a hæmatocele, or an ovarian cyst; but the hæmorrhage which usually occurs in these cases will lead to an exploration of the uterus, which is found to be unimpregnated. The rare coexistence of intra-uterine and extra-uterine pregnancy must be borne in mind.

The recognition of the ovarian tumour is usually easy, as it ordinarily forms a cystic tumour movable apart from the uterus, on a pedicle which can sometimes be detected under anæsthesia. If the tumour is small it may easily escape notice in the lumbar region or may be mistaken for a tumour of the kidney or gall-bladder. Examination under anæsthesia facilitates the diagnosis in these cases. If the tumour is twisted and inflamed it sometimes closely simulates a necrobiotic or strangulated uterine fibroid. Under an anæsthetic its cystic character can usually be made out. Tumours of small size impacted in the pelvis often feel as hard as uterine fibroids, for which they may be mistaken. Rectal examination is of great value in these cases. It must be remembered that uterine fibroids may be as cystic as ovarian tumours, and, on the other hand, ovarian tumours may be solid, and are often associated with hydro-peritoneum, which is rarely found with uterine fibroids. In some cases the diagnosis cannot be made between these two conditions with certainty, though in a patient under 25 a uterine tumour is very unlikely to occur.

If the tumour be ruptured the symptoms will depend upon the nature of its contents. In some cases the accident is followed by few symptoms; in others shock, pain, vomiting, and peritonitis rapidly ensue. If the tumour be multilocular the unruptured portion of the cyst can be felt, and there are signs of free fluid in the abdomen. If the cyst be unilocular the only sign is the presence of free fluid in the peritoneum, which should always be suspected to be due to a ruptured cyst if there are no renal, hepatic, or cardiac causes present. Suppuration of ovarian cysts is indicated by high fever, wasting, tenderness, and occasionally tympanites; a history of tapping or injury during labour is often obtained. Twisted tumours usually give rise to local peritonitis and to fever which usually subsides after a few days; a considerable rise of temperature lasting some days after the acute peritonitis has subsided will usually indicate that suppuration has taken place. Malignant ovarian tumours are fortunately rare during pregnancy. They are usually solid, bilateral, and associated with hydroperitoneum and wasting; secondary nodules may be felt in the abdomen and in Douglas's pouch.

REMARKS ON TREATMENT.

The treatment of ovarian tumours apart from pregnancy is generally acknowledged to be removal as soon as practicable. When pregnancy exists the matter is not so simple; the interests of the child and the desirability of maintaining the fertility of the mother may justify a postponement of the operation. In the introductory remarks a case was mentioned where this was done. In another patient, from whom a dermoid was removed before the occurrence of pregnancy, the other ovary was found to be cystic, but was not removed, as the patient was childless, with the result that in this case also the patient has since had a living child. Case 38 is another illustration of the value of not removing a dermoid. On the other hand, in Case 19 the patient, pregnant for the first time, was operated on for bilateral dermoids at the twelfth week, aborted, and has, of course, remained childless. The tumours were causing no trouble, and were discovered during an examination on account of sterility a few months previously. Had the operation been postponed in all probability she would have had a child; as it was she aborted as a result of the operation.

I should like again to direct attention to the results to the child in this series, according as the operation was performed during pregnancy or after delivery. In cases operated on the infantile mortality was 1 in 3; the abortion-rate, 1 in 3 of the cases operated on in "early pregnancy." In those *not* operated upon during pregnancy, although sometimes unskilfully treated during labour, the infantile mortality was only about 1 in 5, and might have been reduced to 1 in 10 by more skilful treatment during labour; the abortion-rate was about 1 in 10. Five at least (possibly all) of the six cases of bilateral ovarian tumours unoperated on during pregnancy did not abort; both the cases of bilateral ovariotomy during pregnancy aborted. From these figures it appears that operation during pregnancy involves an increased risk to the child. The statistics, based on published cases, in McKerron's classical work, show that the risk of abortion is least in the early months of pregnancy. Although the risk to the child of operation during pregnancy should be taken in most cases, to prevent the grave consequences which may result to the mother from leaving the tumour till the end of pregnancy, yet in uncomplicated cases of small tumours giving rise to no symptoms in patients who are childless, and particularly when bilateral tumours are present, the operation should be postponed, at least until the child is viable.

The treatment of ovarian tumours complicating pregnancy, labour, and the puerperium has been by some writers considered too much from a surgical standpoint; the obstetrical aspect is not less important, and in some cases, as in No. 23, is the dominant factor. Amongst the 19 cases which I have personally treated during pregnancy there were three cases of contracted pelvis which necessitated induction of premature labour in two of the cases, and would have done so in the third had the patient not aborted. It is clear that a contracted pelvis may profoundly modify our treatment, and that an obstetric examination of the pelvis should be carefully made in every case. Then the existence of bilateral tumours in patients who have not had children may justify the postponement of the operation in the hope of obtaining a living child and should lead us whenever possible to conserve some part of the ovary (Case 40).

The following scheme of treatment was published in 1909 (Trans. Amer. Gyn. Soc.). As I have not seen any reason for modifying it, I reproduce it here with slight verbal alterations.

SCHEME OF TREATMENT.

A. *During the First Half of Pregnancy.*

Ovarian tumours should be removed wherever their situation and whatever their size.

Exceptions.—The following tumours should no usually be removed: 1. Lutein cysts complicating hydatidiform mole; these often subside spontaneously. 2. Bilateral tumours causing no symptom if the patient is childless; or, if operated on, part of an ovary should be left behind. 3. Primary adherent malignant cysts. 4. Secondary malignant cysts.

B. *During the Second Half of Pregnancy.*

(*a*) All *large* ovarian tumours and ruptured, inflamed, and strangulated tumours should be immediately removed.

(*b*) Small tumours which are in the abdomen or which can be easily pushed up out of the pelvis in the knee-chest or Trendelenburg position should be watched, and, if no untoward symptoms arise, should be removed either at the end of pregnancy or towards the end of the first stage of labour or after delivery.

(*c*) Small tumours which are incarcerated in the pelvis and cannot easily be replaced in the abdomen may be watched and removed at the end of pregnancy, or, if circumstances will allow, towards the end of the first stage of labour. If the tumours are adherent or solid, Cæsarean section should be performed.

In all ovariotomies during pregnancy the vessels of the pedicle should be separately tied; the pedicle should be ligatured as far as possible from the uterus, and morphia should be given for the first two or three days after operation.

C. *During Labour.*

The best treatment is abdominal ovariotomy, immediate in the case of large tumours, at the end of the first stage or after delivery in the case of small tumours. When the operation is performed at the end of the first stage a second operator may deliver the child by forceps while the tumour is being removed. If the tumour be incarcerated in the pelvis and cannot be pushed up in the Trendelenburg position, the uterus should be withdrawn from the abdomen in order that the tumour may be dealt with.

For solid and adherent tumours occupying the pelvis Cæsarean section may be necessary. It should not be performed for cystic non-adherent tumours. When labour is advanced and a cystic tumour is impacted in the pelvis, the circumstances may render it advisable to deliver the patient by the natural passages after evacuating the contents of the tumour by incision and packing the cyst with gauze; but the tumour should, if practicable, be removed within 24 hours, preferably through an abdominal incision.

Vaginal ovariotomy may be performed in non-adherent cases; but, though simpler in technique, avoiding an abdominal scar and requiring fewer instruments, it is inferior to the abdominal operation in that there is greater danger from hæmorrhage, difficulty in safely tying the pedicle, the necessity of cutting up the tumour, the impossibility of examining the other ovary, and from the presence of the vaginal wound.

Induction of premature labour, forceps, version, and simple tapping of a cyst as means of overcoming the dystocia produced by ovarian tumour are absolutely contra-indicated.

D. *In the Puerperium.*

Ovarian tumours should be removed as soon as practicable, when possible within 24 hours of delivery. If there is doubt as to the aseptic condition of the uterus, a delay of a week or two may be advisable, unless indications of strangulation or infection of the tumour arise, when the tumour should be immediately removed.

INFLUENZA AS AN ÆTIOLOGICAL FACTOR IN NEPHRITIS.*

WITH AN ACCOUNT OF FOUR CASES OF POST-INFLUENZAL NEPHRITIS IN THE SAME FAMILY.

BY W. W. D. THOMSON, M.D., B.SC. BELF., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, ROYAL VICTORIA HOSPITAL, BELFAST;
AND
H. F. MACAULEY, M.B., B.CH. BELF.,
ASSISTANT SURGEON AND ANÆSTHETIST, MATER INFIRMORUM HOSPITAL, BELFAST.

THE appalling ravages of the pulmonary complications of the various influenzal epidemics have naturally tended to divert our attention from another less apparent, but by no means negligible one, nephritis, with which it is the purpose of this paper to deal. Although this complication is not followed by the shocking death-rate of pneumonia, yet in it lurks a serious menace to the future health of the community.

Description of Cases.

In the following series of cases nephritis focussed attention as a sequel in an extraordinary and unmistakable manner, no less than four cases being observed among the children of one family. This household consisted of the father and mother and eight children living in very poor circumstances. The father had a very severe attack of influenza in June, 1918, while the other members of the family were stricken by the malady in the epidemic of October, 1918.

CASE 1.—William, a boy of 11 years, had a typical attack of influenza. After a fortnight he seemed to have recovered, and for almost three weeks he was running about in his usual state of health. At the end of that time his mother noticed a swelling "around his eyes," and two days later this swelling was general over his whole body. He was then taken to the Mater Infirmorum Hospital. On admission to hospital general anasarca was present, the skin pitted on pressure over the whole body, the genitals being so swollen as to be almost translucent. His systolic blood pressure was raised to 135 mm. Hg, but there was no hypertrophy of the heart nor accentuation of his aortic second sound. He suffered from vomiting, anorexia, and constipation, lying in a drowsy, apathetic state, very foreign to his usual temperament, as we found out later. There were no retinal changes present. He still had marked bronchitis resulting from his influenza.

Urine: This boy had always suffered from incontinence, and so it was found impossible to measure accurately the output of urine, but it was evidently very scanty. It was laden with albumin; many epithelial, granular, and blood casts were present, also red blood corpuscles and leucocytes; the reaction was strongly acid.

Under the usual treatment his urinary output increased and his œdema quickly cleared up. His excretion of phenol-sulphone-phthalein, tested two days after admission, was 32 per cent. and the chloride concentration of his urine was high—1·3 per cent. His acute nephritis was evidently of the resolving type, as described by Keith and Thomson,[1] and a good prognosis was given. A few days later all traces of œdema had disappeared and his urine contained only a trace of albumin. When he left hospital, three weeks later, his urine was free from albumin and casts.

CASE 2.—Robina, aged 13, a rather undersized child for her years, worked in the preparing room of a mill on alternate days. She also had a severe attack of influenza during this epidemic, being confined to bed for 18 days. After four days' convalescence she returned to the mill.

---

* A paper read before the Ulster Medical Society.

Six days later she was admitted to hospital with marked puffiness under the eyelids and a marked pad of œdema over the sacral region.

Urine: She was passing on an average 10 oz. daily. Sp. gr. 1016. The reaction was strongly acid and the urine was laden with albumin; very numerous epithelial casts, blood, leucocytes, and kidney epithelial cells were found on microscopic examination.

On the second day after admission she developed a well-marked lobar pneumonia. Her blood, taken on this day, was found to contain 1·95 g. of urea per litre. There was complete retention of chlorides. Owing to her grave condition the excretion of phenol-sulphone-phthalein was not tried, as previous experience in war nephritis had shown that in the acute kidney this procedure was not entirely free from risk.[1] After three days' illness her temperature fell to normal and for the next seven days she improved rapidly; then, without warning, she had six uræmic fits in quick succession. In the intervals between the convulsions her systolic blood pressure was 125 mm. Hg. Her blood, taken at this time, showed that the urea was reduced to 0·33 g. per litre, and the chloride concentration was 1·6 per cent. As these figures showed that her kidneys were functioning well, despite her grave clinical condition, a good prognosis was given. The prognosis was justified, as 12 hours after her last fit her condition of hebetude cleared up, and the normal bright and intelligent disposition was regained.

The albumin in her urine, which up to this had oscillated around 1 g. per litre, began to decrease, and a fortnight later had entirely disappeared. She was allowed up, her urine being albumin-free, but after about three weeks albumin again reappeared in small amount, and on clinical examination at this time her heart was found enlarged; the apex beat was in the nipple line and a mitral systolic murmur was present. Her blood urea, however, only amounted to 0·42 g. per litre. When put back to bed and reduced to a milk diet, after a few days the albumin again disappeared and has remained absent ever since. The hypertrophy of her heart still persists, but no systolic murmur is now heard.

CASE 3.—Irene, aged 9 years, had a very slight attack of influenza. She was the first of the family noticed by her mother to have "become swollen," but the swelling only amounted to a slight puffiness of the lower lids, and occurred about three weeks after her influenzal attack. Since the swelling appeared the mother observed that the child was passing very little urine. On admission there was still present a slight puffiness of the face; the urine contained a trace of albumin, which persisted for almost a fortnight. No functional examination of the kidneys was undertaken.

CASE 4.—Annie, aged 4 years, had a similar history of influenza, followed by a period when she was thought to be quite well. Later, as in the other cases, œdema appeared, and was present on admission. In this case the presence of albumin was inconstant, although the urine contained many epithelial casts, a few blood and granular ones, red blood corpuscles, leucocytes and kidney epithelial cells. Her excretion of phenol-sulphone-phthalein in two hours was 40 per cent., and the chloride concentration of her urine was 1·04 per cent. On departure from hospital three weeks later her urine was normal.

Family Albuminuria: Survey of the Literature.

In all these cases a careful inquiry was made as to the possibility of renal trouble existing previous to the influenzal attack, but the suspicion was absolutely discountenanced in every case. Again, it was thought possible that the nephritis might be attributed to some drug—e.g., phenol (which was largely used in Belfast by the public as a prophylactic)—but no medicine of any description was given, except an entirely innocuous purgative mixture supplied by a neighbouring chemist. None of these children gave a history of scarlatina. A careful clinical examination failed to discover any signs of a recent attack of that disease, such as desquamation, rhinitis, or inflamed tonsils. It is quite possible that these children possessed a familial predisposition to renal disease, an intrinsic weakness of the kidneys, the extrinsic cause of the nephritis being supplied by the influenzal toxin.

This family weakness is also illustrated by an interesting series of four cases of acute nephritis of unknown origin in the same family reported by Benson[2] in 1893. One of the children, aged 12 months, developed general anasarca on April 6th, 1889, and died in uræmic convulsions on May 1st of same year. On April 26th, 1890, another child, aged 4, took ill, and albumin was found in the urine; dropsy appeared in the middle of 1891; this disappeared, but recurred again in the spring of 1892, and the child died in May, 1892. In the same year another child, aged 3, took acute nephritis and died a year later; while in 1893 the baby, aged 13 months, developed the same condition.

A remarkable example of family albuminuria is described by Dr. Newbery Fergusson,[3] in which the father, mother, and eight members of the family had albuminuria, which, however, gave rise to no symptoms. I append the table given in his paper:—

	Female,	alive,	56,	alb.	slight.
	Male	,,	54	,,	badly.
	Female	,,	53	,,	,,
Father, alive, 87, alb. slight.	,,	,,	52	,,	slight.
Mother ,, 78, ,, badly.	,,	,,	51	,,	badly.
	Male	,,	49	,,	,,
	,,	,,	47	,,	slight,
	Female	,,	45	,,	badly.

On inquiry from various practitioners in the city as to the incidence of influenzal nephritis among their patients, it was found that cases of nephritis, more or less severe, and directly attributable to influenza, were by no means uncommon, particularly in those instances where the practitioner followed the routine of examining the urines of his convalescent cases.

Likewise, on a search through the literature, much interesting information on the subject was gleaned. First of all, in the literature of the epidemic of influenza of 1889–91 much diversity of opinion as to the ætiological relationship of nephritis and influenza is apparent. Naturally one's mind is first directed to Leichtenstern's[4] article on influenza in Nothnagel's Encyclopædia.

This authority writes that influenza does not occupy any particularly prominent position as far as the frequency of renal disease is concerned, and is by no means so dangerous to the kidneys as is, for instance, scarlatina, diphtheria, pneumonia, erysipelas, small-pox, &c. Among 439 influenza patients he saw only two cases of acute hæmorrhagic nephritis; in the German army among 55,263 patients only 10 suffered with severe inflammation of the kidneys. However, he continues: "But even at the time I called attention, in my influenza lectures, to the fact that during the months after the termination of the epidemic remarkably many cases of nephritis were admitted, without any ætiological history other than an antecedent attack of influenza. Perhaps these were cases of a post-influenzal nephritis, analogous to those following scarlet fever, tonsillitis, and diphtheria."

Dr. Samuel West,[5] in an address on influenza, says: "Nephritis is a rare complication, and met with rather after than during the acute stage." Likewise Lord,[6] writing in Osler and Macrae's "System of Medicine," states that influenza seems to spare the kidney in the vast majority of cases; in very rare instances has a nephritis been noticed.

Sir Bertrand Dawson,[7] in Allchin's "Manual of Medicine," says: "A large quantity of albumin, with or without hæmaturia, may be present; sometimes it is accompanied by œdema and denotes nephritis, but more often it does not."

Sir J. W. Moore,[8] in the "Encyclopædia Medica," states: "Albuminuria is by no means uncommon in influenza, but nephritis must be looked upon as an infrequent complication or sequela. When it occurs it is a true acute infective glomerulo-nephritis."

Goodhart,[9] in Allbutt and Rolleston's "System of Medicine," writes: "Albuminuria and hæmaturia were not uncommon in the train of influenza, with nephritis as an occasional result."

On the other hand, Grainger Stewart,[10] in his address on medicine at the British Medical Association in 1894, said that "the urinary system was affected in many ways. Sometimes there was a mere passing albuminuria, sometimes a formidable hæmaturia or serious inflammation of the kidneys, and in some epidemics, as in one of those recently described in Egypt, such changes were frequent and in a considerable number of instances proved fatal by uræmia."

Speigelberg,[11] in Pfaundler and Schlossmann's "Diseases of Children," states: "Albumin occurs in 6 per cent. to 10 per cent. of cases, and acute nephritis may develop similar to that in scarlet fever, and cases of the acute hæmorrhagic type have been reported."

Senator,[12] of Berlin, writing in Nothnagel's "Encyclopædia of Practical Medicine," takes a very decided view, and states that influenza, if it does not surpass scarlatina as a cause of nephritis, is at least nearly on a par with that disease.

Fenwick[13] considered that an attack of influenza often proved a touchstone of real value in detecting any weak point or predisposition to disease in the urinary tract.

Watson,[14] discussing the causation of acute nephritis in a series of cases, traces influenza as an exciting cause in 10 per cent.

In a paper entitled "Renal Affections following Influenza" Baumgarten[15] states that he has become convinced that damage to the kidney is a frequent and sometimes serious result of grippe. The form which this damage is capable of taking seems manifold. Apart from transient albuminuria he has found in the train of influenza acute degeneration of the kidney, acute inflammation, both varieties of the chronic diffuse nephritis, and finally cases of persistent albuminuria. An epidemic of influenza thus becomes harmful in a way which is not at once apparent, because the damage to the kidney may not become manifest until the patient is believed to have recovered from the original disease, and the epidemic is forgotten. Baumgarten's contention is confirmed by the statistics of his own life insurance practice. In the five "grippe" years in America (1890-94) he examined 1222 apparently healthy adults, of whom 3·35 per cent. were rejected for albuminuria. In the immediately preceding five years (1885–89), out of 1029, roughly an equivalent number, only 0·77 per cent. were rejected for albuminuria. This result is on a par with Leichtenstern's already quoted observation as to the increased incidence of nephritis in Germany after the same influenza epidemic.

Cases of acute nephritis arising from influenza are also reported in the literature by Mansel Sympson,[16] Piggott,[17] Fraser,[18] Drew,[19] Russell,[20] Ribbert,[21] Strumpell,[22] Krahl,[23] Anton,[24] &c. Fraser drew attention in his case to the great rise in the amount of albumin excreted with the onset of bronchitis.

As regards the recent epidemic the literature on the subject is more unanimous, and the importance of nephritis as a complication of influenza is more clearly recognised.

Herringham,[25] in opening the discussion on influenza at the recent meeting of the British Medical Association, states that in June, 1918, epidemic nephritis was fairly common, but in the autumn epidemic the most *common* complication was nephritis, while in the third wave in February the incidence of nephritis was lessened.

In the report of the influenza epidemic of 1918 in the British armies in France by the Influenza Committee of the Advisory Board to the D.G.M.S.[26] it is stated that the chief complications after the pulmonary were albuminuria and nephritis. In the first few weeks of the epidemic cases were generally reported to be free from albuminuria, but about the same time as pulmonary infection appeared albuminuria also began to be noticed. The Medical Research Committee[27] has already drawn attention to this connexion: "In the winter of 1916–17 a considerable number of cases of nephritis occurred as a complication of the very severe bronchitis and broncho-pneumonia prevalent at the time."

Symonds,[28] in a paper entitled "Nephritis in Relation to the Recent Epidemic of Influenza," describes a series of 22 cases of influenzal broncho-pneumonia complicated with nephritis with 11 deaths, autopsy revealing an acute degeneration of the kidneys.

Colonel Soltau,[29] speaking at the discussion on influenza in the Royal Society of Medicine, said: "Many patients had slumbering or latent nephritis lighted up, and of these the majority died."

In the same discussion Whittingham[30] stated that "albumin was present in 100 per cent. of the cases on the second day of the disease. Casts were present in 50 per cent. cases on the third day to fifth day. The albuminuria gradually diminishes, but if the men are returned to duty too soon after mild influenza there is risk of nephritis developing."

Cole and Rudolf,[31] speaking of the epidemic at Bramshott in September–October, 1918, declared that in almost all febrile cases a mild nephritis developed, the urine containing albumin, red and white blood cells, and granular and hyaline casts. In some cases the urine was bloody and diminished in quantity. Post mortem many kidneys were hæmorrhagic like those of scarlatinal nephritis.

Abrahams, Hallows, and French[32] drew attention to the high percentage of influenzal-pneumonia cases complicated by acute nephritis, and state that such cases would escape detection were reliance placed on clinical evidence alone without examination of the urine. A peculiar feature of these cases (also remarked by Symonds) is the absence of œdema. Without a routine examination of urine influenzal patients might be discharged as cured while still nephritic. It is from cases such as these that Rose Bradford's small white kidney "of unknown origin" later on develops. Post mortem these observers found that the large, red blood-oozing kidneys of the type seen in acute scarlatinal nephritis—an acute glomerular nephritis—were constant in their appearance in fatal cases.

In civilian practice Davies[33] records three cases of acute nephritis following influenza, with two deaths from uræmia. He also remarks that chronic nephritis is a more common sequel than acute nephritis.

Solfre of Naples[34] emphasises the frequency of nephritis in severe cases of influenza, and notes the constancy of this complication in fatal cases, while Dalimier[35] lays great stress on the prognostic importance of the renal functions. He states that the severe and rapidly fatal cases were those in which albuminuria was most marked. This is also the opinion of Sir John W. Moore,[36] who measures the gravity of a severe attack by the intensity of albuminuria.

Post-mortem the kidneys, as described by Douglas Symmers,[37] of New York, were found enlarged and congested, the capsule was tense and stripped easily, leaving a dull injected surface which bulged considerably beyond the cut edge of the capsule. Microscopically a diffuse cloudy swelling of the epithelium, especially of the convoluted tubes, was present.

There is, therefore, a very considerable weight of evidence to prove that influenza is a very important ætiological factor in nephritis. Its recognition as such means a further encroachment on the ever-diminishing domain of so-called idiopathic nephritis, and in this connexion the view ably advocated by Professor H. B. Day,[38] that war nephritis is but a complication of trench fever, may be recalled.

Conclusions.

1. That nephritis is a more frequent complication of influenza than is commonly thought.

2. That the virus of influenza may affect the kidneys in various ways: (*a*) By producing a temporary albuminuria as seen in many other acute infectious fevers. (*b*) By causing an acute nephritis during the course of the disease, especially if respiratory symptoms are present. (*c*) Nephritis may arise during convalescence, as in scarlatina. The damage to the kidney may not become manifest until the patient is believed to have recovered from the original disease. (*d*) A dormant or latent nephritis may be lighted up.

3. Nephritis may follow even mild cases of influenza.

4. Nephritis occurring during the course of influenza may be masked by the respiratory symptoms, and only careful routine examination of the urine may demonstrate its presence, while some of the cases arising after the symptoms of influenza have abated may show such slight symptoms—transient œdema, slight oliguria, or capricious albuminuria—that they may easily be missed.

5. That the urine in this disease should be frequently tested not only during the disease but also during convalescence.

6. That probably the frequency and severity of this complication varies in different parts of the world and in different epidemics.

7. That in the next few years we may expect in examination for life insurance to find a higher percentage of albuminurics.

THE FACTORS CONCERNED IN ASTHMA AND THEIR TREATMENT.

BY D. W. CARMALT JONES, M.D. OXON., F.R.C.P. LOND.,
PROFESSOR-ELECT OF SYSTEMATIC MEDICINE, UNIVERSITY OF OTAGO.

THIS paper is an attempt to formulate a working hypothesis as to the various pathological conditions which underlie the clinical phenomena of asthma and to suggest treatment appropriate to each of them, treatment aimed rather at prevention of the paroxysm than at its relief.

Definition of Asthma.

It is necessary first of all to make some definition of the title asthma and decide how much is to be included in it.

Hyde Salter's book begins with the words, "Spasmodic asthma—paroxysmal dyspnœa of a peculiar character, generally periodic, with intervals of healthy respiration between the attacks." This may be taken as authoritative, but this author regarded the phenomenon as a disease, whereas at present most physicians consider it as a symptom, and as such it is considered in this paper.

The word asthma is now used, at any rate by most patients, in a fairly extended sense, including paroxysmal dyspnœa from many causes and also something more than paroxysmal dyspnœa. A healthy man after violent exercise is short of breath; a person suffering from heart disease is short of breath on slight exertion; but where there is no restriction to the breathing, which is rapid and copious, and when each breath gives some relief, the condition might, if there were not already too many distinctions of the kind, be called *polypnœa* rather than *dyspnœa*. The asthmatic, however, suffers from definite *dyspnœa*, each breath is difficult, and is performed against resistance. The dyspnœa occurs in paroxysms independent of obvious external cause like exercise, and in well-established cases a condition of mild chronic dyspnœa is found in which the accessory muscles of respiration are constantly employed. This chronic condition is closely associated with emphysema, but is to be distinguished from the relatively rare condition of gross obstruction of the large respiratory passages from within or without.

The word asthma is therefore used here to include spasmodic attacks of difficult breathing, without obvious exciting cause, which lead to a condition of mild chronic dyspnœa with exacerbations. It is a respiratory symptom that occurs in bronchitis, heart disease, renal disease, and alimentary disease, and also as a pure neurosis—in fact, in one or other disorder of all the great physiological systems.

A respiratory symptom is a disturbance of the respiratory function, which is said to be controlled by the respiratory centre in the medulla, and it should be admitted that for the physician such "centres" are used as a convenient hypothesis rather than as the accurately localised points on which the experimental physiologist founds his work. The respiratory centre is normally stimulated to activity by the presence of carbonic acid in the blood. It controls the neuro-muscular apparatus whereby the lungs are filled and emptied, some parts of which are constantly in use, and others, the accessory muscles, are held in reserve to reinforce respiration whenever increased action is acquired. But the respiratory muscles can be controlled by other means than the CO_2 content of the blood. Their movements can be modified at will, and they are capable of the most refined and highly coördinated voluntary action, as when used by expert singers. No other of the great visceral systems is under like control for a purpose quite distinct from the discharge of its essential functions, and since this voluntary control exists it is liable to hysterical disturbance. Hysterical mutism and aphonia are common phenomena, and all observers are agreed as to the large neurotic element in asthma. Attacks of spasmodic dyspnœa, frequently nocturnal, have been observed by the writer among troops suffering from war neurasthenia; it is one of the visceral disturbances of that condition, and may be regarded as due to an instability of the respiratory centre.

If one may be allowed to postulate an unduly irritable state of the respiratory and other visceral centres, a working hypothesis for asthma is readily constructed. The respiratory centre has its normal stimulus in the CO_2 content of the blood, and the respiratory movements are also subject to voluntary control, but the centre can also be reached by other routes. Sneezing and coughing are both reflex modifications of respiration, and indicate that there is an afferent path to the centre from the respiratory mucous membrane. But the act of sneezing can be induced by looking at the sun, so that yet another surface, the conjunctiva, must have afferent connexions with the respiratory centre.

Analogy with Hay Fever.

Much light is thrown on the problem of asthma by consideration of the cognate problem of hay fever, about which a good deal of accurate information exists. When the grass is in flower and its pollen is in the air some persons suffer from the persistent sneezing attacks which are called "hay fever." The pollen falls on the nasal mucous membranes of the whole community, but only a small proportion suffers from hay fever; these patients are hypersensitive to pollen, and at any time of year a drop of watery extract of pollen instilled into the conjunctival sac will induce in them an attack of sneezing. They are especially susceptible to a toxin in the pollen, and by appropriate subcutaneous injection they can be immunised against it.[1] The question arises whether in such patients it is the respiratory or the vaso-motor centre which is disturbed; it might well be the latter, vaso-dilatation and effusion occurring at the site of absorption, and sneezing being induced by the exudation as it would be in a healthy person. Probably both centres are stimulated, and the point is worth noting, since bronchial vaso-motor turgescence and bronchial muscular spasm have both been held responsible for the phenomena of asthma. The average hay fever subject is only susceptible to the pollen of a few grasses, which are specific for him, but more sensitive persons can be stimulated by a greater variety, by the pollen of some flowering plants, by the effluvia of particular animals, and so on. The specificity of certain toxins is also traceable in asthma. We have therefore to think of a respiratory centre closely associated with a vaso-motor centre, and both liable to be excited to action in a reflex manner by means of a specific toxin.

The study of hay fever establishes, or at least suggests, the following facts:—

1. The respiratory centre is abnormally irritable in some persons.
2. An association exists between the respiratory and vaso-motor centres, so that both may be excited by a single peripheral cause.
3. This suggests the possibility of a general association of the visceral centres.
4. The respiratory centre may be excited by impulses from the respiratory mucous membrane with the precipitation of a reflex act.
5. The respiratory centre may be excited by stimulation of a mucous surface which is separate from the respiratory system.
6. Specific chemical substances exist which readily stimulate the respiratory and vaso-motor centres when applied to mucous surfaces.

These observations may be applied to the problem of asthma in the following way:—

1. *The over-excitable respiratory centre.*—Chronic bronchitis is one of the commonest diseases in this country, but the association with it of asthma of any severity is not very frequent, the percentage of chronic bronchitics who have spasmodic dyspnœa is not very high, and one may reasonably postulate an over-excitable respiratory centre for these patients, since they suffer from a particular disturbance of the function of breathing which others, with a similar morbid condition of the lungs, do not. An irritable centre goes far to explain the asthma of renal disease, where excretion is imperfect, and noxious chemical substances are retained in the circulation; these may readily disturb such a centre, whose normal stimulus is the CO_2 content of the blood.

2. *Association of respiratory and vaso-motor centres.*—Hyde Salter claimed that the asthmatic paroxysm was due to spasm of the bronchioles; this is supported by its immediate relief by morphia. Others have regarded it as due to vaso-motor turgescence, and this view is supported by the relief given by adrenalin. Vaso-motor disturbance is obvious enough in hay fever, with its suffused eyes, and by far the most probable explanation is that both centres are closely associated and one not affected without the other.[2]

3. *General association of visceral centres.*—The asthma of cardiac disease suggests a further association of visceral centres, the cardiac centre, upset by the impulses coming from a diseased heart, affecting an associated respiratory centre.

4. *The respiratory centre aroused by irritation of the respiratory mucous membrane.*—The cough of bronchitis is the common instance of this, and the fact that the great majority of cases of asthma are bronchial in origin demonstrates the effect of chronic irritation of the bronchial mucosa on the respiratory centre of the susceptible.

5. *The respiratory centre aroused by irritation of other mucous surfaces.*—This almost follows from Section 3, but is more clearly demonstrable. The precipitation of asthmatic attacks by indigestible food is a common occurrence, and a case is quoted below where the attacks were directly traceable to the presence of a tapeworm, and ceased with its removal. Irritation of the afferent nerves from the gastro-intestinal tract appears to induce disturbance in the respiratory centre, just as irritation of the conjunctiva does in hay-fever subjects.

6. *Specific chemical substances affecting the respiratory centre.*—Ten years ago the writer conducted some experiments in the treatment of chronic

---

[1] Noon: THE LANCET, June 10th, 1911, p. 1572: Freeman, THE LANCET, Sept. 16th, 1911, p. 814.

bronchitis by means of vaccines in Sir Almroth Wright's laboratory at St. Mary's Hospital. In the course of this work an organism was isolated from the sputum of a female patient suffering from bronchitis and severe asthma. She agreed to try the results of inoculation treatment, and a vaccine was prepared and injected, the patient being instructed to return in a few days. She reported on returning that though the cough was no better the breathing was much relieved; treatment was continued, and the improvement was maintained for many months, when the patient ceased to attend hospital and was lost sight of. The same vaccine was extensively used, for the hope was entertained at the time that the cause of asthma had been discovered. About 100 patients were treated and 50 attended for treatment with some regularity, with the result that about 35 showed improvement in the frequency and severity of their attacks.[2] That is to say, a considerable number of patients who suffered from bronchial asthma underwent improvement of that symptom on immunisation against a specific micro-organism found in the bronchial mucus.

This presents a close analogy with what occurs in hay fever, the symptoms of which are known to be due to a specific poison acting on a mucous membrane connected with the respiratory centre. The inference is that this organism produces a toxin which irritates the afferent bronchial nerves in such a way as to induce either bronchial spasm or vaso-motor turgescence or both. It has never been possible to guarantee improvement by the use of a vaccine of this organism and it is improbable that it is the only one concerned, its description therefore need not be repeated here, but these observations indicate that the asthmatic paroxysm itself may depend on the toxins of certain bacteria acting on a susceptible centre. Some sensitive patients are rendered asthmatic with any form of inflammation of the mucous membrane, in others definite kinds of infection are required. The successful treatment of asthma by cauterising the nasal mucous membrane and so destroying the nerve-endings of a particular area and thus preventing the passage of afferent impulses to the centre proves how slight a lesion may be required to set off the paroxysm and indicates the careful surgical treatment of all accessible abnormalities in the naso-pharynx.

Points in Treatment.

(1) *The respiratory centre.*—In the treatment of any case of asthma the points to be considered which emerge from the foregoing are as follows: The respiratory centre, the state of viscera outside the respiratory tract, the state of the respiratory mucous membrane: they are all illustrated in the accounts of cases which follow. The physician should seek means to depress an irritable centre, to remove sources of irritation from mucous membranes outside the respiratory tract, and to treat all abnormalities of that tract itself whether by surgery or therapeutic immunisation.

The following case is one of purely hysterical disturbance of respiration:—

A patient suffering from "shell shock" was examined in a hospital in France. His general appearance at first sight suggested pneumonia; the respirations were 120, with a pulse-rate of 80; he was mute and paretic. While under examination an aeroplane passed over the tent and the patient's attention was distracted for a few moments, during which the respirations fell to a much slower rate, but rose again when the machine was out of hearing. The mutism and paresis were removed in the usual way by demonstration and re-education, during which time the breathing became normal.

Another asthmatic patient definitely dates the onset of attacks from some shock in the trenches, being blown up and buried, or the like. A third patient, whose case is quoted below, never suffered from asthma, although the exciting cause was present, until the London air-raids began. A fourth, also quoted, follows an occupation in which work is light at the beginning of the week, but accumulates towards the end, each day being heavier than the preceding; in his bad periods the attacks were always more severe towards the end of the week. In such a case the use of sedatives is clearly indicated, and this man experienced definite improvement after taking bromides at night.

Sedative drugs and re-education should therefore be employed as required where the centre is at fault and under imperfect control.

(2) *Mucous membranes outside the respiratory tract.*—The following case is an instance of asthma largely of intestinal origin:—

CASE 1.—W. M., aged 33. Has suffered from a tapeworm for the last five years. Two years ago, during air-raids, she suffered from bronchitis as a result of going out not fully clad; the bronchitis was associated with paroxysmal dyspnœa. Has an established cough, with nocturnal dyspnœa, cannot lie flat, and never sleeps the night through. She states that the dyspnœa was always worst during air-raid periods, and was always severe after a heavy meal taken at night. There is bony obstruction in the nose: it is not complete, but the passage is imperfect; the palate is narrow, though not extremely so. The accessory muscles of respiration were at work, but there were no other physical signs of disease. She was admitted to Westminster Hospital. In the absence of any bronchitis of severity it was assumed that the asthma as at present existing was due to intestinal irritation, and the usual anthelmintic treatment was given, with evacuation of many segments of a tapeworm, but, unfortunately, the head was not passed. The result has been a complete relief of the asthma; the patient can lie flat in bed and sleeps the night through.

This patient is a typical instance of spasmodic dyspnœa kept up by irritation outside the respiratory tract. She has a narrow palate, a condition frequently associated with epilepsy, and nervous instability in general; it was a common experience at the war that persons of this type stood war-strain very badly; an irritable respiratory centre is therefore not surprising in such a case. It was found that the nervous strain of the air-raids precipitated the attacks as soon as she suffered from bronchitis. Added to this, the associated narrow base of the skull produces narrowing of the bony passages of the nose, and obstruction to breathing, in itself a source of peripheral irritation, and, finally, the gross irritation of the tapeworm kept the attacks going. The removal of the latter has stopped the asthma; if the worm recurs the attacks will probably recur likewise. If they recur independently the proper procedure will be operative treatment of the nose. This was suggested to a surgical colleague for immediate action, but he did regard it as indicated.

(3) *Surgical conditions of the respiratory tract.*—This patient (Case 2) had very definite abnormalities of the nose and throat. He was seen shortly before the war, and surgical treatment was undertaken with some immediate benefit. He is, however, subject to such remarkable variations in condition

---

[2] Brit. Med. Jour., Oct. 9th, 1909.

according to the locality in which he is living, that no weight can be attached to the apparent results of treatment. It was clearly correct practice to have his respiratory abnormalities surgically treated in view of his respiratory symptoms, but the whole history is stated as a warning against hasty inferences.

CASE 2.—D. A., aged 18 when first seen. Asthma of three years' duration. Sudden onset with a "cold," went to play tennis, and could not do so owing to dyspnœa. Attacks are chiefly nocturnal; in an attack simply cannot get breath; some cough, but no expectoration. Patient is extremely susceptible to locality, being free at the sea and on high ground, but much more liable when near any quantity of fresh water, such as lakes or rivers. On examination, some constant dyspnœa with over-action of the scalenes was found, but no physical signs in the lungs; there was, however, a good deal of abnormality in the nose and throat, septic tonsils, adenoids, and enlarged middle turbinal bones. This condition was treated surgically, and bad asthma followed for the first few days. Examined about a fortnight later the breathing was found much improved, and the patient remained free for some months.

In reply to a request for further information the patient very kindly supplied the following:—

October, 1913.—Operation throat and nose in Middlesex.

November, 1913.—Went to Liverpool, and was there till November, 1915. Fairly well, and suffered very slightly. Could play cricket and tennis.

September, 1914.—Had severe attack at Carnarvon for about 48 hours. During autumn not too well, and advised not to join the army.

January, 1915.—Joined army (saying nothing about asthma). Trained first outside Liverpool. Quite well.

April.—Went to Conway (N. Wales). Very well. Weighed 12 st. stripped. (I only weigh 11 st. in clothes now.) Went up Conway mountains, &c.

November.—Went to France. Quite all right. Never suffered in the trenches even when waist-deep in water. Could always sleep. No exertion ever brought on an attack.

July, 1916.—Got mixed up with gas shells (tear gas) and swallowed a good deal. About ten days after started very severe attack lasting five days. Went to hospital and came to England. Sent to Manchester, and after two weeks convalescent home sent on leave. No treatment apart from usual medicine.

August.—On leave. Went to Norfolk and had bad attack. Went to West Kirby, Cheshire. Had severe attacks biweekly. Private doctor there first used adrenalin chloride. Very good results, but only lasted about 8–10 hours.

September.—Had medical board at Hounslow (very bad at the time), more leave. Severe attacks kept on, and had adrenalin fairly frequently.

October.—Had medical board and asked to go back to duty. Went to Hull. Within a fortnight had another very severe attack. Sent into Hull Infirmary. Out in ten days (usual medicine) and went on leave.

November.—Slightly better while on leave, but I couldn't stop in Middlesex; always made me bad. Went back to Hull and at once ill again with the worst attack ever experienced. Sent into infirmary again.

December.—Came out of infirmary and passed fit for general service at once. Finally, I was allowed leave pending overseas instructions, [illegible] I couldn't stand Hull.

January, 1917.—Went overseas. Landed at Boulogne feeling bad. Went up to Etaples feeling worse. After 24 hours there I was sent to hospital again.

February.—After three weeks in hospital I came back to England and went to hospital in London.

March.—Sent into convalescent home at Bournemouth. There eight weeks. Much better, and could sleep, and weight increased.

End April.—Rejoined regiment outside Hull.

End May.—Went overseas again.

End July.—Had very severe attack while outside Nieuport with my regiment. Sent to hospital and then to convalescent home at Dieppe.

August.—Transferred to Flying Corps. Base medical board kept me at Etaples till orders came through. During that time I was frequently quite bad.

Beginning November.—Came home to England for R.F.C., and was passed by Hampstead medical board as fit for pilot. I had to argue with them for a long time as I admitted having asthma.

January, 1918.—Started flying. Fairly well. Obtained certificate, &c.

May to September.—Instructing near Cambridge. Frequently very bad, but never went sick; kept going somehow. Used adrenalin. On occasions I have only got to the aerodrome (400 yards from mess) after making three halts on the way, and then had hardly enough strength to climb into the aeroplane. Felt better up in the air, but, of course, I was sitting down and keeping still. I always considered being in the air made breathing much easier.

October.—Went to Norfolk. One very bad attack again.

November-December.—Trotting the country; fairly well.

January-March, 1919.—At Hythe. Much better. Hardly any sign.

April.—Demobilised. Still keeping well. Stayed down near Dover several times and felt well.

April-December.—Bristol. To start with I was much better and did some rowing during the summer, and actually raced in a regatta. In September I had some attacks. In end October, in Middlesex, I had a very severe attack again. Much better now. Middlesex never suits me, and I'm always ill there. I never started asthma till I came there. I consider London and the south-east coast (Margate, Dover, &c.) as the places I have felt really well in. There is no doubt that the gas shells made all the difference to me, as for nine months in France prior to July, 1916, I was very well and fully capable of doing duty with an infantry regiment. Flying seemed to do me good. I've been up to 13,500 ft. and felt quite all right. I don't think my operation was much benefit, nor was cauterising. I consider I'm much better now than I was in 1916, 1917, and 1918, and am hoping I am gradually leaving it behind.

4. *Inflammation of the respiratory mucous membrane.*

CASE 3.—W. H., seen in 1913. Increasing asthma for ten years; attacks are much affected by food and patient has to live very plainly. There is some bony obstruction in the nose, which was once cauterised with benefit lasting about six months. No abnormality was detected in the chest. It was decided to try the effect of inoculation, and a streptococcus and coliform bacillus were isolated from the sputum and employed. This patient suffered much more in periods of mental stress: the heavier his day's work the more liable he was to attacks. He was accordingly treated with bromides, to be taken at night when overworked, with a good deal of benefit. Further, there was some difficulty in bringing up sputum, which was benefited by lemonade taken at bedtime, the idea being that any substance which decreases the coagulability of the blood likewise decreases the viscidity of all discharges, and thus makes these more readily expelled. This patient remained under treatment for about nine months, having injections every week for about two months, the interval being gradually extended to a month. The number of attacks recorded in succeeding weeks were as follows after treatment was begun for the first three months:—

October—	1st wk.,	2 attacks.	November—	3rd wk.,	0 attack.
,,	2nd ,,	2 ,,	,,	4th ,,	0 ,,
,,	3rd ,,	7 ,,	December—	1st ,,	1 ,,
,,	4th ,,	1 attack.	,,	2nd ,,	1 ,,
November—	1st ,,	3 attacks.	,,	3rd ,,	1 ,,
,,	2nd ,,	3 ,,	,,	4th ,,	1 ,,

January, February, March, April, May, June, no attacks; July, 15 attacks.

During this time "tightness" and wheezing in varying degrees used to occur, but stopped short of what the patient calls an "attack." This July relapse occurred just before the outbreak of war, and the patient was not seen. Treatment was, however, continued by Dr. Braxton Hicks, and in 1918 he wrote to the following effect. There was some return of asthma in the summers of 1916 and 1917, when conditions of work were particularly trying, but these were cut short by resumption of inoculations, which he forthwith took quarterly. "I have had no bronchitis, not a common cold even, for three years or more." He wrote again, on a request for a report, in October, 1919:—

"There have been several spells of six and nine months of complete freedom; the old tightness has lessened. For the last three years I have been able to do a lot of cycling and some rowing ...... neither of which I could do comfortably before. ...... This year I had a fortnight by the sea with no symptoms whatever of asthma, although sea air was always bad for me before, and I swam again with no ill-effects. ...... Since my return there has been some asthma, not much, but sufficient to show that I am not entirely free."

This case appears to be one in which the irritable centre is clearly present, the irritability being increased by nervous stress. The most important peripheral condition is the bronchitis and when that is kept in abeyance by suitable immunisation the patient is free; he is fortunate in that his infecting organisms have been easily isolated and he has responded well. The immediate response to a few very small doses of vaccine, quite insufficient to cure an established bronchitis, make me regard his case as one in which the organisms produce a special toxin which precipitates the paroxysms as does the pollen in hay fever.

Conclusion.

In the treatment of asthma, therefore, one has to consider an irritable centre, hysterical influence of that centre, infections of the bronchi and parts of the lungs below them, more especially with specific bacteria whose toxins induce the paroxysms, abnormalities of the respiratory tract superior to the bronchi, and irritation of viscera outside the respiratory tract altogether.

For the centre, the use of sedatives, and the usual psychical methods applicable to hysteria must be employed as required. For the nose and throat surgical methods are generally needed, and appropriate treatment must be given to other visceral disturbances.

As to the respiratory tract proper, bronchitis must be treated in some way or other. If patients can afford to be sent to the high Alps, to the Sahara, or for winter cruises in the Mediterranean, well and good. If they are less fortunate and have to earn their livings under unfavourable conditions, some definite therapeutic attempt must be made to deal with the condition. It is a bacterial infection, and in all recovery from such infections the natural capacity of the body to elaborate antibodies is required, for which the only therapeutic measure we possess is treatment by appropriate vaccines; finally, if the hypothesis as to the specific character of certain bacterial toxins in the inducement of asthma is correct, that cause also can frequently be combated by the employment of vaccines.

It is submitted that this constitutes a scheme for the treatment of the asthmatic state on rational lines.

NOTES OF A SERIES OF 103 CASES OF

COMPOUND (GUNSHOT) FRACTURES OF THE FEMUR

TREATED AT A GENERAL HOSPITAL IN FRANCE.

BY PHILIP TURNER, M.S. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON, GUY'S HOSPITAL.

GUNSHOT fractures of the femur, the gradual evolution of their treatment, and the great improvement in the final results, form one of the most interesting chapters of military surgery during the recent war. The extremely interesting book by Lieutenant-Colonel M. G. Pearson and Captain J. Drummond on "Fractured Femurs: their Treatment by Calliper-Extension" gives an admirable account of the later phases of the femur problem, and it was after reading this that I thought that a brief account of a series of fractured femurs treated at an earlier date at a general hospital in France might be of interest. Indeed, it is only by considering series of statistics from Casualty Clearing Stations, general hospitals abroad, and home hospitals at different periods of the war that a true idea of the improvements brought about can be realised. Statistics of end-results alone may give a false impression unless there is also some information as to the mortality and the amputation-rate before the end-results are attained. On this subject Colonel Pearson and Captain Drummond throw some light, for they are able to tell us that even in 1918 the total mortality in field ambulances and Casualty Clearing Stations was about 20 per cent., and that, in spite of the short stay of these cases in hospitals in France for the last four or five months of the war, the mortality at all hospitals on the lines of communication taken together was 10·8 per cent. and the amputation-rate 10·2 per cent. It would be interesting to know the mortality and the amputation-rate at casualty clearing stations and at home hospitals for this same period.[1]

In the evolution of the treatment of fractured femurs three periods may be recognised. In the first, which occupied about the first year of the war, the treatment was very much on the old lines, but observations were being made, facts recorded, and means for meeting septic and other complications were being sought for.

In the second period, which extended from the summer of 1915 to about the beginning of 1918, new and improved methods of treating both the wounds and the fractures were being devised and perfected. The Thomas splint became the standard apparatus for treating these fractures; the suspension method was devised by Major M. Sinclair; towards the end the calliper method of procuring extension was introduced, as well as many other contrivances for overcoming the septic infection of the wounds, for improving the position of the fractures, and for obtaining in the end a good functional result. I particularly wish to emphasise the work done during this period, for there is a tendency for it to be overlooked. As a matter of fact, I believe that practically all the methods which gave such greatly improved results during 1918 were really devised during this second period.

The third period commenced about February, 1918, and was characterised by the provision of a specially equipped femur hospital for each area in France, and later by similar hospitals at home, where the developments and improvements of the preceding period were systematically and thoroughly carried out with such excellent results.

Description of Cases.

The series of cases under present consideration, amounting to 103, were treated in No. 3 General Hospital between July 1st and Dec. 31st, 1917; they were originally collected for the purpose of providing information to the authorities, with reference especially to mortality and amputation-rates. The cases were consecutive and include all cases of complete fracture with solution of continuity, from the neck of the bone to the condyles. In many cases there were other wounds as well, but all are included in the series. Cases where amputation had been performed before admission are omitted. Cases of partial fracture or where metal fragments were embedded in the bone without complete fracture are not included; wounds of the knee-joint with fracture of a portion of a condyle are also not included. It will be noticed that this series comes into the second, or intermediate, of the three periods, before the establishment of special femur hospitals, when these cases were treated at any L. of C. hospital to which they happened to be sent, and before special appliances were generally available. The patients practically all came from the Ypres district, which accounts for the exceptionally septic character of the wounds; most of them were wounded during the attack on the Paschendaele ridge in the autumn of 1917. Of the 103 cases I have fairly full notes of about 30, brief notes with X ray tracings of another 35, while of the remainder I have simply records of the nature of the injury, the duration of their stay in hospital, and their ultimate disposal.

---

[1] Since the above was written an address by Sir Anthony Bowlby on Gunshot Fractures of the Femur has been published in the British Medical Joural, Jan. 3rd, 1920, p. 1. This gives much new information as regards amputation-rates and mortality at casualty clearing stations, general hospitals, and home hospitals.

1. *Treatment Before and Condition on Admission.*

As a general rule the men had been wounded two or three days before admission. A few had been wounded on the previous day, while in others the interval was a few days longer. The latter had either been kept for a few days at the C.C.S., or had had a long period of "lying-out." Generally speaking, at the clearing station the wounds were excised and drainage provided, with removal of loose fragments of bone, and sometimes of the missile, the patients being then at the earliest opportunity sent on to a general hospital. With one or two exceptions the limb was put up from the first on a Thomas splint.

In all the 103 cases the wounds were septic, and in most of them grossly so. There were three cases of massive gas gangrene and a good many cases of local gas cellulitis which proved amenable to treatment. In a good many the limb was so swollen that it occupied the whole space between the side bars of the Thomas splint. Several of these I have noted as cases of "threatened gas gangrene," but, though a local gas cellulitis was present, massive gas gangrene did not develop, and the limb recovered with free incisions and drainage. The splinting of the fractures on arrival was nearly always unsatisfactory. The extension bands, which had been glued to the side of the leg and tied to the end of the splint, were almost invariably slack, so that there was no extension, and the ring of the splint was often an inch or more below the tuberosity of the ischium. Under these circumstances the splint acted rather as a sort of tray on which the injured limb rested. The expression "no extension, position bad," occurs again and again in those cases of which I have full notes. I have no doubt that the extension was satisfactory when the patients left the C.C.S., and that subsequent stretching of the bands, combined with the unavoidable disturbance of the splint during transport, was responsible for the unsatisfactory condition on arrival. Various methods of dressing had been employed, but there was very little to choose between them, except that those in which the Carrel-Dakin method had been employed were rather worse on account of the tendency to provide insufficient drainage.

2. *Method of Treatment.*

As soon as possible after admission an X ray examination was made with a view to ascertaining the nature and position of the fracture and the presence of any metal fragment. As a rule, no X ray examination had been made at the C.C.S. owing either to the absence of the apparatus or, more often, to the pressure of work. The result was that in many cases, though the wound had been excised and drainage provided, the metal fragment had been left in situ. Metal fragments, most of them removable, are present in 24 out of 55 tracings of X ray plates. As soon as this examination had been made an anæsthetic was given, the wound explored, any loose fragments of bone removed, any retained metal fragment sought for, and freer drainage provided, if thought desirable. The splint was readjusted and extension obtained, in most cases, by means of a spring. As a rule, owing to the swelling of the limb and the condition of the wound, it was impossible at this time to get the fragments into satisfactory position, but usually, after ten days or so, swelling and sepsis had been overcome to such an extent that it was possible to adopt means for improving the position of the fracture. There is no need here to describe the particular methods employed, as this has already been done.[2]

The Thomas splint was employed as a routine apparatus, but in three cases a long Liston splint was used for a time, and in one or two an abduction frame. In all these the position of the wound prevented the satisfactory application of the Thomas. Generally the splint was used with the true "Thomas" action with counter-extension from the tuberosity of the ischium, but in a few cases the "Hodgen" was obtained by suspending the splint from an extemporised support attached to the foot of the bed. It must be remembered that at this time suspension frames, such as were afterwards fitted in the special femur hospitals, were unobtainable. To give an example of the difficulties that one was confronted with, I had for six months been trying to get some Sinclair "net beds" for treatment of these cases but without success. Officially they were unknown, and it was not until nearly a year after they had been ordered that these beds arrived. It may also be mentioned that callipers were not generally available until the spring of 1918, though this method of obtaining extension had been introduced some months earlier.

3. *Duration of Stay in Hospital: Mortality.*

All cases were kept until active sepsis had subsided, the temperature had become normal, and the danger of secondary hæmorrhage had passed. Excluding those who died and those where amputation was required, I have a record of the length of stay in hospital of 76 cases, the average being 52 days. In the great majority of cases there was fairly firm union before discharge. I have notes of four cases in which the wounds had entirely healed before transfer to home hospitals, and I know there were two others. Of the four cases one healed after primary excision of the wound and suture, one after secondary suture, and the other two by granulation. All the men when evacuated to home hospitals were still fitted with Thomas splints.

The 103 cases were made up of 15 British officers, 58 British other ranks, and 30 German prisoners of war, including two officers. The deaths were as follows: British officers, 2; British other ranks, 6; Germans, 6; total, 14 (13·59 per cent.). The higher mortality among the Germans is due to the fact that most of them had been lying out for a long time, and on this account their condition, both local and general, was very bad on admission. The above includes all deaths from whatever cause between admission to hospital and evacuation to home hospitals, a period averaging about 7½ weeks. The condition on discharge was such that there was probably little or no subsequent mortality.

---

[2] Gunshot Fractures of the Femur, Some Methods of Overcoming Serious Displacements THE LANCET vol. ii., 1918, p. 74.

The cause of death in each case was as follows :—

1. Capt. —. Also injury to pelvis and rectum. Toxæmia. 2. Lieut. —. Septicæmia. 3. Pte. —. Also wounds of pelvis and testicle. Toxæmia. 4. Pte. —. Also fracture of the tibia and fibula of the other leg and fracture of the humerus. Secondary hæmorrhage from wound of the arm followed later by secondary hæmorrhage from leg. Probably septicæmia. 5. Pte. —. Gas gangrene. 6. Pte. —. Gas gangrene. 7. —. Secondary hæmorrhage. 8. Pte. —. Also G.S.W. buttock and abdomen opening bladder. Secondary hæmorrhage. 9. Lieut. von —. Septicæmia. Nephritis. 10. Pte. —. Also injury to pelvis. Gas gangrene. 11. Pte. —. Septicæmia. 12. Pte. —. Secondary hæmorrhage. 13. Pte. —. Streptococcal septicæmia. 14. Pte. —. Secondary hæmorrhage.

It is possible to compare these figures with the mortality at an earlier date, since there were admitted to the same hospital, between March 1st and Dec. 31st, 1915—that is, at the end of the first and at the beginning of the second of the three periods—54 cases of fracture of the femur with 8 deaths (14·88 per cent.). As the greater number of those were treated before I joined this hospital I can give no details of this series, but I know that the stay in hospital was often only a few days, and that the men arrived on long Liston splints, and were usually sent away on abduction frames, though in some of the later cases the Thomas splint was employed. Although the mortality appears to be only slightly higher than it was some two years later, there was, owing to the short period the patients were kept in hospital in France, a very high mortality and amputation rate in home hospitals. In January, 1916, the Medical Research Committee issued a Memorandum which threw light on this by recording the late results of two series of cases treated in home hospitals during 1915. The first series consisted of 96 cases, in 6 of which amputation had been performed in France. Of the remaining 90 cases, 13 were amputated after arrival in England. Five cases died after amputation, and 8 other cases terminated fatally, giving a mortality of 13 in 90 cases (14·4 per cent.). Of the second series of 105 cases, 16 required amputation after arrival in England, of which 7 died; 4 also died without amputation, giving 11 deaths in 105 cases (10·5 per cent.). A consideration of these figures shows the great improvement effected during the second of our two periods.

Amputation Rate.

This varied considerably at different hospitals, and in some was, I believe, for a time as high as 25 per cent. Conservative methods were employed as far as possible in all the cases of the present series, and amputation was performed only in 5 cases, of which 1 died. The following were the reasons for amputation :—

1. Pte. —. General condition on admission very bad. Wound very septic. Recovery. 2. Gnr. —. Amputation for secondary hæmorrhage. Died. 3. Pte. —. Wound extremely septic. Toxæmia. Recovery. 4. Pte. —. Amputation immediately after admission for severity of injury and sepsis. Recovery. 5. Pte. —. For non-union and poor general condition. This patient had a severe fracture of the lower third of the femur with great loss of soft parts. Though septic at first the wound cleaned up well and the fracture was got into very good position. He was kept in hospital over six months and at the end of this time there was no attempt at union, and the wound of soft parts had become stationary. As his general condition was poor and all power of repair seemed to have been lost, the leg was amputated. He subsequently did well.

The last case was the only one kept for anything approaching so long a period, and, with the complete absence of reaction, I feel sure that the fracture would never have united.

Shortening.

Owing to the difficulty in accurately measuring the length of a limb on a Thomas splint I kept no complete record of the amount of shortening on discharge. Colonel Sir William Thorburn, however, carefully measured a number of these cases, and in 23 consecutive fractures found an average shortening of 2·4 cm. (1 inch = 2·54 cm.). This probably gives a fair idea of the shortening in the whole series, as the cases measured were in no way selected, but included many very severe as well as more favourable fractures.

The estimation of the amount of shortening is not without difficulty, and the measurements by various observers of the same cases often show discrepancies. A series of measurements by an independent observer in a large number of cases can, however, be relied upon to give an approximately accurate result. The difficulty in the case of fractures of the femur is chiefly that the measurements taken are not between subcutaneous bony landmarks of the femur itself, but between subcutaneous portions of other bones the relation of which to the femur is variable. The usual method is to measure the distance between the anterior superior spine of the ilium and the tip of the internal malleolus of the tibia. It is obvious that in this method the length will vary according to the position of the hip and knee-joints. Even if the limbs be placed in apparently the same relative positions there may be some tilting of the pelvis which alters the position of the two hip-joints, and this is difficult to eliminate when the injured limb is on a Thomas splint, and partly concealed by bandages and dressings. Another method is to measure from the anterior superior spine to the top of the patella. The same objection as to the possibility of tilting of the pelvis arises here, and in addition contraction of the quadriceps may raise the patella quite half an inch.

In later cases I attempted to overcome these objections by measuring from the top of the great trochanter above, to the base of the head of the fibula below, since there is, unfortunately, no definite bony tubercle on the subcutaneous surface of the external condyle. The top of the great trochanter can always be identified, and forms a satisfactory landmark at the upper end of the bone. The head of the fibula is also easily identified; a prominent tubercle at its base forms a better landmark for measurements than the tip. Provided that the points are carefully identified, and are marked on the skin with a blue pencil, and that the measurements are taken with a rigid measure fitted with a sliding indicator, I believe that this method gives more reliable results than the others. It is, of course, only applicable when the fracture is below the great trochanter. To test the possible extent of the variations in different positions I have made a series of measurements of normal legs with the hip and knee-joints in various degrees of flexion, abduction, and adduction.

In measurements from the trochanter to the head of the fibula the position of flexion of the knee-joint is the only one which causes serious variation, but this position is both easily recognised and readily corrected. It might be thought that movements of the hip-joint would have no effect, but one often finds that the inward and outward swing of the trochanter in complete abduction and adduction respectively gives a trifling variation, usually slightly longer than when the hip is straight. These variations are, however, trivial when compared with the measurements obtained by the other methods.

The following table shows the variations in the measurements (in inches) of a normal limb, by the various methods, in different positions of the hip and knee.

—	Ant. sup. spine to int. mall.	Ant. sup. spine to patella.	Great trochanter to head of fibula.
Leg straight	$33\frac{3}{8}$	$16\frac{3}{4}$	18
Hip flexed 20°	$32\frac{3}{4}$	$15\frac{7}{8}$	18
Flexion of hip and knee 20°	33	$16\frac{1}{4}$	$17\frac{3}{4}$
Hip fully abducted ...	$32\frac{1}{8}$	$15\frac{1}{4}$	$18\frac{1}{8}$
Hip fully adducted ...	34	$16\frac{5}{8}$	18
Internal rotation of hip	$33\frac{5}{8}$	$16\frac{7}{8}$	18
External rotation of hip	$33\frac{1}{2}$	$16\frac{5}{8}$	18

I have to thank Colonel Sir William Thorburn for his kindness in reading through and criticising the present paper.

TREATMENT OF
A CASE OF NARCOLEPSY.

BY CHARLES S. MYERS, M.D., SC.D. CANTAB., F.R.S.,

SOMETIME CONSULTING PSYCHOLOGIST, BRITISH EXPEDITIONARY FORCE.

FOR various reasons I should not have thought of publishing this case of functional "sleeping attacks" had it not been for the recent correspondence (THE LANCET, Dec. 27th, 1919, and four following weeks) on the drastic treatment of a similar case recorded by Dr. Hildred Carlill (THE LANCET, Dec. 20th, 1919). I did not hesitate to describe his recourse to trephining as "absolutely indefensible" in the light of modern psychotherapy. Dr. Carlill, in his reply, not unnaturally complained of my strong language, and accused me of scant courtesy, insisting on the purity of his motives and asking for an "outline" of some "alternative treatment." I used strong language only because such obsolete and perilous treatment demanded it, but I had no intention to be discourteous nor to throw doubt on the excellence of Dr. Carlill's motives. An alternative treatment I offer here.

Description of Case.

This patient had served as a subaltern in the Royal Air Force, from which he had been recently discharged before he came to me, as suffering from "minor epilepsy." The "sleeping fits," he said, had begun in 1918 during convalescence from malaria, and he attributed them to the large doses of quinine (180 gr. in two days) which he was then given for his cure. These "fits," he wrote me, "were at first of short duration, gradually becoming longer and more frequent as time went on. There were also periods when my mind was a blank, but these periods and the fits seemed to have no connexion with one another. The fits seem to be of two types: the 'conscious' type, in which, although quite aware of all that is going on around me, I suddenly lose all use of my faculties and am unable to respond in any shape or form; and the 'unconscious' type, in which the fits are usually more violent and sometimes last many hours. In the latter type, although I have not been aware of it myself, I have at times given way to what appeared to be terror, and I have spoken in a strange language, believed to be Malay, which I understand slightly. These fits, whether conscious or unconscious, have invariably taken place when I am either sitting or lying down, often during conversation or in the performance of some act, never when standing up. There has never been any warning sign save occasionally a tendency for my gaze to fix on some small object in the room. After the attack I feel slightly dazed, as if I had been in a deep, heavy sleep."

When, in the course of a brief visit to his neighbourhood, I was asked to see the patient, he had been for some weeks under the observation of a well-known expert in psychotherapy, who, however, in the course of three or four interviews, had elicited little or nothing that seemed likely to throw light on the causation of the fits. The patient was obviously of an extremely nervous disposition, and at the time of my visit was much worried over financial and domestic troubles. He seemed an honest and capable young fellow. During the war he had had several exciting experiences, one of which is worth mentioning here for its connexion with the subsequent results of mental exploration.[1]

He was on a ship off the Azores, when he heard a cry in the water. Rescue proved impossible, and later "No. 3 greaser"—a Chinaman—was found to be missing from the crew. The patient discovered that the Chinaman must have been bound in sacking, secured by a rope, and thrown overboard; also that the victim had been winning large sums of money by gambling with his compatriots. The patient believed that the latter suspected him of having evidence which would incriminate them of the murder.

The patient also confessed to me that he had always been afraid of the dark, and that he was still afraid of it. Just before I saw him, he had had two "sleeping fits" of the unconscious type within two or three days, and it had been observed that both these fits were ushered in by his assuming a peculiar attitude of the arms, the left arm and fingers being outstretched in front of the body, the right arm being flexed at the elbow and kept close to the side with the fist firmly clenched.

Treatment by Exploration.

I resolved at once to make use of this observation. I said to the patient,

"Now I want you to compose yourself, and to get into a comfortable dreamy state. When you are in this state of reverie I am going to put your arms in a certain position, and I shall want you to tell me what comes into your head. Never mind how absurd or inconsequent it may seem, you must tell me at once what ideas occur to you."

The patient had not been told of the already described attitude which had marked the onset of at least the last two fits. When I placed his arms in the position described he at once gave me the following information in a dreamy unemotional manner:—

"Out shooting. After a small bird or animal. Came face to face with an orang utan. Within two or three yards of it. Shot it dead. Before it died, it crushed up some big sticks. I went up to it thinking it was dead. It made a grab at me."

---

[1] I use the word "exploration" in this paper as offering a truer description of what is generally termed "analysis," and as being free from the implications of the various psycho-analytic schools.

On being further questioned, he said that the incident had occurred in Borneo, that he had never thought or spoken of it since until that moment, and that no other European was with him at the time. He could not recall the part of Borneo where he met the orang, nor how it was that he was away from other Europeans, nor what natives, if any, he had with him.

I felt that there was more in this incident than I could elicit from the patient. Accordingly, as time pressed, I sat him in a more comfortable chair, telling him to fix his gaze on my finger and at the same time suggesting to him that he would become more and more drowsy. In a few seconds he suddenly passed into a sleep so deep that I realised that he was in one of his "sleeping fits." I was quite alone with him and was somewhat disturbed by the recollection that I had been informed that he was apt to offer violence if attempts were made forcibly to rouse him from such fits. I found that loud noises failed to produce any effect. I thereupon tried strong persuasive efforts and soon succeeded in inducing a condition in which he would sleepily reply to my questions. I extracted piecemeal the following information, with considerable trouble in overcoming obvious resistance.

> "I was near the M—— River in Borneo, out shooting deer. I turned a corner and found myself face to face with an orang. I don't know who was the more frightened, he or I. I tried to use my rifle, but I was too close to do so. With great difficulty I got out my automatic pistol and shot the orang. He fell down. I went to feel his face. It was such an odd, hairy face. He made a grab at me. I jumped to one side, to the left. He made another grab at me, half sitting up. He would have got me if I had been wearing trousers instead of breeches and puttees. The orang then clawed down some thick branches and started to break them up. It made me feel horribly sick. I shot him again through the forehead, this time dead. I returned to the hut very sick and giddy. I tried to tell the natives in the hut all about it, and I wanted them to go back and to bring in the dead orang. But I did'nt know enough of their language and could'nt make them understand."

I suggested to the patient that he would wake with full knowledge of all that he had told me. But before rousing him I determined to see if I could discover the origin of his fears of darkness. His memory at once turned to a night when he awoke in the dark terrified at finding his favourite gollywog close beside him. He was then about four years old, and he recalled the entry of his elder sister into his room to comfort him and to stop his cries.

On waking from hypnosis, he re-told me all that I had learnt from him. I explained to him that he had been to sleep and had dreamed and told me of it while asleep. During his account I now put his arms in the position already described, and he at once realised that that was his attitude when, confronted at close quarters with the orang, he tried to get at his automatic pistol. He laid special stress now on the cry of the dying animal. "I was horrified: it was all so human, like the cry of a man." He gave me this account without emotion throughout, but with obvious interest and willingness—in marked contrast to the dreamy tone of the sentences I had wrung from him under strong persuasion during hypnosis.

I asked him why he had never thought or spoken of the orang incident since the day of its occurrence, but he could not give me any explanation. I asked him whether he felt at all differently since he had told me of it. He replied that it seemed as if a great load were off his mind. Before he left me to bicycle home (a distance of four miles) he told me of two other experiences—his fear of a face at the window, and his inability to read two stories in "Sherlock Holmes."

A Second Investigation.

The latter I have had no opportunity of pursuing, but the former was investigated by me on the following day, when he paid me a second visit. My first question was as to how he felt, because the improvement in his general appearance and demeanour was so obvious. He replied that he arrived home on the previous evening feeling extraordinarily vigorous in mind and body. His wife at once noticed his improved spirits. He lifted her from the floor—a feat he had never before attempted—and he felt unusually happy. I was to-day informed that when a sudden noise happened to occur in a room in which he was he would often look round suddenly at the window. He could give no explanation of this beyond faintly associating the face at the window with that of a Chinaman. Naturally I asked him if this Chinaman was "No. 3 greaser," but this did not seem to be the case. I decided to hypnotise him. He passed, with less readiness than on the previous day, into hypnosis, whereupon I elicited from him in the same dreamy unemotional tone as before the following story:—

> "I knew the Chinamen on board suspected me of knowing too much about the death of 'No. 3 greaser.' I feared that they meant to kill me to save their own skins—later several of them were convicted—and consequently I used to lock my cabin door at night. My cabin was on deck with a skylight roof. One night I awoke thinking I had heard a slight noise. I looked up and saw a Chinaman's face peering in through the skylight window. I raised an alarm and the face vanished."

I suggested that he should recall this on waking, but before I woke him I proceeded to investigate two other matters, of which I had been just informed. These were that on the last occasion of his attack (when he assumed the aforementioned position) he was playing with a dog, and that on the penultimate occasion he was opening a cupboard as the attack began. I therefore questioned him under hypnosis as to what he had experienced just before the last attack occurred. He described how he was playing with a dog, which to his knowledge disliked being teased, and that he pulled its tail, whereupon it tried to bite him. "And then?" I asked. "Then I thought of the orang utan." On the occasion of the penultimate attack he suddenly thought, he told me, of his father, over whose ill-health he was greatly worried. I regret that I did not try to ascertain the relation of this thought to the orang's death. On waking he re-told me all that I had elicited from him, and he informed me that he had never thought or spoken of the cabin incident from the time of its occurrence to that day. Of course, he had not been previously aware of the association of the attack with the thought of the orang.

These were the only two occasions I had of treating the patient. More than 12 months have passed since then. Quite recently (Jan. 24th) he wrote me that as the result of my treatment he has felt "both mentally and physically different," and he thinks that "the number of sleeping fits since then only number four or five, all of which have been of a very mild character, and have taken place quite recently, so that they may be accounted for as due to the excess of personal worry to which I have of late been subjected." These worries were, as before, of a financial and domestic character. Into them I had not the time to enter closely, nor did I attempt to explore various other sources of mental disturbance elicited during my brief inquiry.

The consequence of my two interviews with the patient is that, instead of remaining a relatively useless member of society, he has now been occupied for several months in receiving a technical training at a large engineering works; and there can be little doubt that under appropriate conditions and with fuller treatment he will make a complete recovery.

Remarks.

The interesting features of this case are :—

1. The dependence of the narcoleptic attacks on the tendency to revival of certain memories repressed from consciousness. Probably the "conscious" type of fits depended on a weaker resistance against a less forceful intrusion of such memories, and the "blank" periods occurred during "subconscious" concentration on those memories.

2. The immediacy of the amnesia. Why, we may well ask, were the memories of the orang and cabin incidents immediately lost? The answer appears to be this: The sudden strong emotion which was aroused induced a change of personality, the patient passing into a so-called "somnambulistic state," on passing out of which all recollection of the events therein occurring was repressed.

3. The striking and immediate relief obtained by the restoration of the repressed memories to full consciousness.

4. The absence of emotion during the return of the lost memories, even the resumption of the arm attitude evoking no emotion. This and numerous other cases in my experience offer no support to the view that for a successful cure emotional "abreaction" is essential during the revival of dissociated memories. I believe this view to be based on the mistaken hypothesis that what is primarily repressed in "functional" amnesia is the *emotional* component of the experience. I wish to suggest that it is the *unpleasant*, not the emotional, component that is directly repressed (or inhibited), and that the resistance against revival expresses the inability to admit the unpleasant, not the inability to face the emotion. In every-day life we forget not the emotional component of experience, which may be pleasant or unpleasant, but the unpleasant component, which may be emotional or unemotional. By bringing the same explanation to bear on the present case and on similar "functional" cases, we link up a normal with a pathological process of forgetting. Because of its concomitant unpleasant tone, it is the cognitive experience which is *repressed*, while the emotional component is merely *dissociated*, is left free to wander into other fields of cognition, and may thus or by well-known ruses manage to re-enter consciousness.

5. The value of hypnosis in immediately eliciting memories which an expert physician had been unable to revive after several sittings with the patient fully awake. A dreamy state is, as every psycho-therapeutic practitioner knows, the most effective for the process of reassociation. There is, however, no fixed line between the state of reverie desirable in every mental exploration and that of hypnosis, into which, indeed, any patient may quite spontaneously pass during such examination.

6. The value of exploration as compared with suggestion. Suggestion merely presents a motive for an action contrary to that which it sets out to cure. But it is a well-established fact of experimental psychology that one process does not destroy, but can at most merely inhibit, an antagonistic process, and that, other things being equal, the older tends to outlast the later acquired activity. Exploration, on the other hand, is a far more radical operation than suggestion, whether it be suggestion by trephining or hypnotic suggestion. Exploration is, in my opinion, the main, if not the only, ground for recourse to hypnosis. Suggestion, whether practised under hypnosis or in the waking life, is comparable rather to a stimulant or to a counter-irritant, whereas exploration attempts to probe the cause to its very origin, resting on the belief that repression and dissociation are at the root of the disorder and that redintegration alone can effect a true cure.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

GALYL IN THE TREATMENT OF POST-MALARIAL ANÆMIA.

BY J. GRAHAM FORBES, M.D., D.P.H. CANTAB.,
M.R.C.P. LOND.,
AND
R. F. LUNN, L.R.C.P. & S. EDIN., L.R.F.P.S. GLASG.

Dr. A. G. Phear, in his interesting article published in THE LANCET of Jan. 24th "On the Treatment of Malaria in Macedonia," makes reference to the use of galyl. The result of the use of galyl in the following case closely corresponds with the beneficial action claimed by Dr. Phear on the post-malarial conditions :—cachexia, anæmia, and splenic enlargement.

A private in the Royal Serbian Army, aged 27, was admitted to the —— General Hospital at Vertekop, under the care of one of us (R. F. L.), on Jan. 10th, 1918, suffering from marked anæmia, bronchitis, and pain in the chest of two months' duration. No reliable history could be obtained of any rigor or vomiting nor of his having received quinine treatment. On admission he was very anæmic, his complexion being of a pale lemon-yellow tint. Temp. 98° to 99·6° F. There were signs of bronchitis in the lungs, and he was very breathless on the slightest exertion. The spleen was definitely enlarged, but there was no evidence of enlargement of the liver, and no œdema. He was given a tonic mixture of iron, arsenic, and strychnine three times daily, and an expectorant mixture from Jan. 10th to 29th. During this period his temperature fluctuated irregularly in the daily rises from 99° to 100°, 101° and 102°, more often between 100° and 101°.

A blood film examination made on Jan. 14th failed to show any malarial parasites. The condition of the red cells gave evidence of his marked anæmia by the presence of degenerated cell forms and megalocytes. In a second examination made on the 23rd the search for parasites was equally unsuccessful, nor were any particles of hæmozoin pigment found. The following complete count was obtained :—

Reds	1,520,000	Hb	30 per cent.
Whites	3,600	Colour index	= 1·0

Differential count in percentages :—

Polymorphonuclears...	35	Small lymphocytes ...	54
Large lymphocytes ...	10	Eosinophils	1

In counting 100 leucocytes 4 nucleated red cells were seen (3 normoblasts and 1 megaloblast). There were also marked inequalities in size (anisocytosis) and chromatophilic changes of the red cells.

As the patient was evidently making no progress on the tonic mixture, quinine was administered in daily intramuscular doses of 15 gr. on Jan. 30th and 31st and Feb. 1st, and subsequently by the mouth in doses of 20 gr. each day from Feb. 2nd to the 7th. The temperature, which had remained at about 101·6°, showed no change till Feb. 2nd, when it fell to normal. On Feb. 9th, as the patient was still very anæmic, it was decided to administer galyl. Before doing so, however, a blood examination was made and yielded the following count:—

Reds	1,940,000	Hb	40 per cent.
Whites	6,000	Colour index ...	= 1·03

Differential count in percentages:—

Polymorphonuclears...	49	Transitionals...	1
Small lymphocytes ...	30	Eosinophils	2
Large lymphocytes ...	16	Myelocytes	2

In counting 100 leucocytes, 8 nucleated red cells were seen (7 normoblasts and 1 microblast). The red cells also showed poikilocytic and anisocytic forms and chromatophilic degeneration, but no parasites or pigment particles were seen.

Galyl (0·4 g.) was then given intravenously in 20 c.cm. of sterile solution of sodium bicarbonate. The temperature, which had been normal from Feb. 2nd to the 9th, rose during the course of the day to 100·2° but fell to normal on the 10th. The patient rapidly showed improvement, and on Feb. 16th a further blood examination gave evidence of the satisfactory response to treatment:—

Reds	3,250,000	Hb	65 per cent.
Whites	6,300	Colour index	= 1

Differential count in percentages:—

Polymorphonuclears...	41	Transitionals...	4·5
Small lymphocytes ...	40	Eosinophils	3
Large lymphocytes ...	11	Basophils	0·5

In counting 200 leucocytes, 1 normoblast only was seen. The red cells showed some variation in size and shape and chromatophilic changes, but no parasites or pigment particles could be found.

On Feb. 21st a second dose of 0·4 g. of galyl was administered intravenously as before.

The patient continued to show marked and rapid improvement in colour and general health. The temperature remained normal and the spleen could no longer be felt. On March 1st a blood count gave the following figures:—

Red	3,990,000	Hb	80 per cent.
Whites	7,500	Colour index ...	= 1·02

Differential count in percentages:—

Polymorphonuclears...	47	Eosinophils	7
Small lymphocytes ...	29	Basophils	3
Large lymphocytes ...	11	Myelocytes	2
Transitionals...	1		

No nucleated red cells were seen and there was much less evidence of irregularity in size and shape of the red cells.

Unfortunately this was the last blood examination made before the patient was finally discharged on April 4th, 1918, quite well, looking fat, robust, and of good colour: in fact, improved beyond all recognition.

The patient was subsequently readmitted to the hospital in the autumn, having been slightly wounded in the course of the final Serbian offensive in October, 1918. He then looked extremely well and had put on weight. There had been no recurrence of malaria and the spleen could not be felt.

In the failure to discover malarial parasites it would, perhaps, be rash to describe the anæmia in this case as a post-malarial condition; for such an assumption might well be regarded as unjustified and open to grave doubt despite the fact that quinine produced an alleviation of the febrile condition. With this reservation, however, we feel fully entitled to attribute the man's cure to the use of galyl, whether his anæmia was a post-malarial condition or not.

NOTES ON A CASE OF

PANCREATIC INSUFFICIENCY.

BY J. O. SYMES, M.D. LOND.,
PHYSICIAN TO THE BRISTOL GENERAL HOSPITAL.

THIS case appears to be worth recording as it presents many interesting problems, both of physiology and pathology.

The patient, a man about 40 years of age, first came under treatment in 1888, when he suffered from renal colic and ultimately passed a calcium oxalate stone. He enjoyed fair health until 1905, when, after some attacks of gout, it was found that the urine contained sugar and a trace of albumin. The amount of sugar varied from 1 to 5 per cent, and finally in 1911 it and the albumin disappeared. During this period he again passed a stone of calcium oxalate. Early in 1911 he began to have diarrhœa with offensive stools. This continued for six months and he lost much weight. In August, 1911, when he was in a nursing home having a sebaceous cyst removed from the back, it was noticed that the stools contained oil. A skiagram of the pancreas was taken, and a calculus was clearly shown in the duct of the gland. A second and third skiagram confirmed this. A month later whilst at Eastbourne the patient was seized with an acute attack of pain in the lower part of the abdomen, with vomiting and diarrhœa. The vomiting and acute pain lasted for six hours, and he was confined to bed for several days. During the next few months the abdominal pain, diarrhœa, and fatty stools persisted, and it was decided to operate with a view to removing a pancreatic calculus.

However, the pain became less acute, and skiagrams taken in April and May, 1912, showed no trace of the calculus in the pancreatic duct. The operation was therefore abandoned, but as the patient's general health was declining, and as the stools were still frequent, large, fatty, and offensive, he went into Dr. Combe's Clinique at Lausanne. Here he derived considerable benefit, partly from the use of hydrochloric acid and pepsin after meals and partly by adopting a more farinaceous diet. By the end of the year he was passing only two motions a day, and these were free from visible oil. There was no sugar or albumin in the urine. Occasionally during his stay he suffered from attacks of acute abdominal pain.

During 1913 there were some attacks of fever of several days' duration. There was no explanation of these attacks, but they were marked by an increase in the number of stools and by the passage of large quantities of oil. Patient revisited Lausanne during 1913 and 1914, and was more especially benefited by this last visit. His weight had dropped from 15 st. 2 lb. to 12 st. 5 lb.

From this period until the time of his death five years later the patient was greatly troubled by diarrhœa, four or five motions a day, of which the odour was extremely offensive; they were clay-coloured, loose, frothy, and at times looked like pure linseed oil. They were very difficult to retain and gave rise to pain and soreness at the anus. The analysis of the fæces always showed an excessive amount of connective tissue and striated muscle, enormous quantities of fat, and increased amounts of fatty acids and soaps. He was able to get about freely, and for the next five years his weight remained unaltered.

In 1916 it was first noticed that the blood pressure was excessive (310 mm. Pachon), and no measures taken succeeded in reducing it below 250 mm. The amount of albumin in the urine increased slightly, and on one occasion there was a trace of sugar in the urine. In 1918 he passed three renal calculi (calcium oxalate). Dropsy appeared in April, 1919, and four months later, in his seventieth year, he died from cardiac failure with very extensive œdema.

This case lends support to the view that oxaluria may arise from the fermentation of carbohydrates in the digestive tract. In this instance the faulty digestion of starch was due to the insufficiency of the pancreatic secretion. The first bout of oxaluria occurred 30 years before the patient's death, and probably at this time there was commencing fibrosis of the pancreas. Seventeen years later oxaluria recurred, and with it glycosuria and albuminuria. The glycosuria was never severe, and six years later, when he was carefully dieted, it disappeared, to return only on one or two occasions when he had broken his dietary regimen. It was an alimentary glycosuria, and to the end of his life the patient preserved sufficient pancreatic substance to prevent the appearance of the signs and symptoms of diabetes.

The stone in the pancreatic duct which gave rise to the acute attack during the autumn of 1911 was possibly an oxalate stone. Apparently it ulcerated its way out of the duct into the bowel. The characteristic stools of pancreatic insufficiency were noted some months before there were symptoms of a stone in the duct. The fact that the symptoms and signs became more pronounced after the stone had disappeared was due, no doubt, to cicatrisation and gradual narrowing of the lumen of the duct, and the ever-increasing fibrosis of the pancreas.

Other points of interest are: (1) The rapid and ultimately fatal rise of blood pressure due to auto-intoxication from the bowel or to imperfectly antagonised suprarenal secretion. (2) The long-continued good nutrition and physical and mental energy shown by the patient, which indicates to how great an extent pancreatic digestion may be assisted by other organs. (3) The relief afforded to the patient by withdrawing fat from the diet and giving acid preparations by the mouth (acidol pepsin, betain chloride) after meals, the increased acidity stimulating the flow of secretin, and thus increasing both the internal and external secretions of the pancreas.

A CASE OF

ACUTE TOTAL INVERSION OF THE PARTURIENT UTERUS.

By H. TOWNSEND-WHITLING, M.B., B.S. DURH.,
AND
NORMAN GLOVER, M.B., B.CH. OXON.

THE following case is worthy of record, in which total inversion of the uterus occurred acutely four hours after delivery, and reduction was fortunate in achieving complete recovery.

The patient was a primipara of 28 years, who had been delivered of a male child, 7½ lb., at 11 A.M. on Dec. 22nd. Labour was normal and not excessively prolonged; presentation R.O.A. There was some feebleness of contraction of uterus afterwards, but the placenta was expelled unaided. There was only slightly excessive loss of blood. At 7 P.M., as she was still losing and complained of after-pains, the nurse in attendance got rid of an apparent intra-uterine clot by massage and compression of fundus. At 10 P.M. a catheter was passed and urine drawn off. Nothing else abnormal was noticed. Pains, however, continued from that time, becoming stronger and more expulsive in character, and at 1 A.M. one of us (N. G.) was summoned and found the whole uterus extruded from the vulva and the patient suffering from shock. Morphia gr. ¼ was given, the extruded uterus wrapped in gauze soaked in hot lysol solution, and general restoration treatment applied. At 3 A.M., on the arrival of the other partner (H. T.-W.), the entire uterus was lying outside the vulva, the placental surface of attachment being anterior and to the left. Hæmorrhage was not great, chiefly consisting of general venous oozing, and a large triangular piece of membrane could be seen spread over the uterine surface to left and inferiorly, to which two small ovoid placentæ succenturiatæ were attached. The uterine mass measured roughly 9 in. in transverse and 10 in. in vertical diameters. The patient being placed transversely across the bed and deeply anæsthetised, the uterine surface was thoroughly flushed with very hot lysol solution, and I (H. T.-W.) then stripped off the membrane with the attached placentæ succenturiatæ. Little bleeding resulted. After considerable effort the uterus was replaced inside the vagina, when severe shock occurred, and strychnine was given hypodermically. Reinversion of the uterus proved exceedingly difficult. Rupture of the vaginal walls was greatly to be feared, the vagina being already fully distended by the tumour, and the introduction of the hand still further increased the tension of the walls. Compression and manipulation of uterus backwards and upwards was useless, so the whole mass was thrust forwards and upwards into the axis of brim under deep anæsthesia. Gradually the uterus began to infold and the cup above to diminish until the latter half of its inversion occurred suddenly. Shock then, at the moment of complete reinversion, was very great. Pituitrin 0·5 c.cm. was injected and acted rapidly, and a hot intra-uterine douche of lysol was given, and the lateral and posterior fornices and vagina were packed firmly with sterilised gauze. Prophylactic injection of mixed puerperal antistreptococcic serum was given. A few hours afterwards the patient passed urine naturally. The only sequela was a temperature of 101° to 102° F. on Dec. 25th, which disappeared after the vaginal plug was removed and an intra-uterine douche given.

Remarks.

We had not before seen the third stage of acute post-partum inversion of uterus, which is stated in Eden's Midwifery to occur only once in 180,000 to 200,000 cases of child-birth. The first and second stages have both been met with and treated by me (H. T.-W.), but only after some mechanical interference with the cord still attached to an adherent placenta, or very forcible attempt at manual expulsion of placenta or clot.

In this case two factors appear to arise: (1) The overlooking of pieces of membrane with placentæ succenturiatæ attached; (2) efforts made to express a clot, doubtless resulting from a poorly contracted uterus and continued oozing from the first factor.

I should estimate this reduction as being by far the most difficult of all obstetrical manœuvres. The uterus gets rapidly swollen and enlarged, and the over-stretched vulva nips it so tightly round the false pedicle that even the replacement within the vagina is very difficult, and the want of room in the over-distended vagina greatly cramps the operator's hands. The only possible way to re-invert it, in my opinion, is to picture and follow in retrogression the pelvic axis, the slightest deviation from which produces a total block and a useless expenditure of force. Three distinct moments of shock appear. First, when the uterus is extruded from vulva; secondly, on vaginal replacement; thirdly, on the rather sudden completion of reinversion of uterus, which at the end is like the sudden expansion of a deflated india-rubber ball. Both the second and third shocks I could anticipate by touch and give warning to Dr. Glover, who most skilfully induced a very deep anæsthesia for me in the last stage.

These notes are written in the hope of helping others placed unexpectedly in a similar predicament.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

THE VALUE OF ALCOHOL AS A THERAPEUTIC AGENT.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 17th, Dr. H. H. DALE, the President, being in the chair, when a discussion was held on the Value of Alcohol as a Therapeutic Agent.

The PRESIDENT, in opening the discussion, said that he could only attempt a judicial review of the evidence as to the modes of action of alcohol which could be derived from pharmacological experiment, and left it to those who continued the discussion to make clear to what extent this evidence was applicable to the action of alcohol as seen in practical therapeutics. With regard to the form in which alcohol was administered, although other constituents might affect the rate of absorption, he was sceptical as to the importance sometimes attributed to the minute traces of ether and other constituents of wines and distilled liquors. They might affect the flavour of the spirit and to some extent its directly irritant action on mucous membranes, and thus indirectly the rate of its absorption, but he thought it had still to be proved that they did more. There seemed justification, therefore, for discussing the effects of ethyl alcohol as such rather than those of the various liquors containing it, which were generally used for its administration.

Action of Alcohol as a Food and as a Drug.

The known actions of alcohol might be divided into: (1) its action as a food; and (2) its action as a drug. It must now be regarded as beyond dispute that alcohol could be used by the body as a source of energy, and in that limited sense it could act as a food. Atwater and Benedict had shown that for a limited period as much as one-fifth of the body's total requirement of energy could be supplied in the form of alcohol. The body could oxidise considerable amounts of alcohol and thereby use it as an immediate source of energy in place of a calorific equivalent of carbohydrate or fat. This, however, did not commit us to the view that alcohol was a desirable source of energy for the body of the healthy person. Considered merely as a source of energy, alcohol had some peculiarities which might recommend it, in certain conditions, in preference to the normal non-nitrogenous elements of a diet. 1. It required no digestion. This was also true of dextrose. 2. It was very rapidly and completely absorbed. 3. It was not susceptible, as were the carbohydrates, to fermentation by yeasts and bacteria, with the formation of troublesome amounts of gas or an undesirable acidity. It would be expected, therefore, that in conditions in which the digestive secretions were deficient, in which absorption was retarded, in which bacterial decomposition was likely to be excessive and troublesome, the mere food value of alcohol should give it a place in rational therapeutics. It should be able to supply to a system temporarily unable to obtain it from normal sources the minimum of energy necessary to enable it to carry on and tide over a critical period. Alcohol was used purely as an emergency source of energy in the preliminary period of starvation which introduced the modern treatment of diabetes. It would be of great interest to know to what extent alcohol in this condition was really an essential factor in the treatment, and to what extent it merely helped to blunt the patient's sense of monotony and deprivation.

Alcohol as a Stimulant.

When alcohol is used as an item of the convalescent dietary it was not its food value but its drug properties which were being employed. Many would probably be familiar with the prolonged controversy which divided the world of pharmacology on the question as to whether alcohol had any scientific claim to its popular reputation as a stimulant. One school, headed by Binz, were concerned to find experimental support for the action of alcohol as a respiratory and circulatory stimulant, which the prevalent clinical practice suggested. Such evidence as they produced was subjected to destructive criticism by Schmiedeberg and his followers, who failed to find evidence of any action by alcohol which was not accounted for by its depressant action on the activity of the higher centres, or by its directly irritant action on mucous membranes. The school of Schmiedeberg had the better of the argument, and more recent work, using more modern methods, had produced evidence of the same general tendency. No evidence had been produced of a direct action of alcohol on the heart or on the circulation, which would be regarded as having any significance, apart from preconception due to clinical practice. A recent careful examination of the effect of alcohol on the excitability of the respiratory centre in normal men, produced no evidence of any stimulant action. Certain relatively trivial effects on the circulation could usually be detected. Immediately after a dose of alcohol had been swallowed the pulse showed a brief acceleration, but, as Professor Dixon had pointed out, this was not due to stimulation of the heart by alcohol, but a reflex effect of the mild irritation of the buccal and pharyngeal mucous membranes. It was generally agreed also that in man alcohol caused a dilatation of the skin vessels; the mechanism of this action was not clear, but it could not, in any case, be regarded as a stimulant action on the circulation. In the case of the action of alcohol on the higher brain centres, there was a consensus of opinion in favour of the view that the action was not due, as popularly supposed, to a stimulation of cerebral activity, but to a depression of the inhibitory control which the higher brain centres normally exercised.

The most important point which the discussion might help to illuminate was the apparent discrepancy between this pharmacological conclusion that alcohol was in no direction a true stimulant, and the still prevalent use of alcohol in therapeutics to remedy a depression or threatened failure of the circulation and respiration. He expected that the discussion would produce testimony from personal experience in favour of the view that alcohol had real value in certain conditions of this kind.

In considering the apparent discrepancy between experimental evidence and clinical experience it must be remembered that practically the whole of the experimental results had been obtained on normal subjects or normal organs. It might be suggested that the pathologically weakened heart or depressed respiratory centre was differently affected from those of the normal subject. He thought there was no warrant for such a suggestion, or that it was necessary to suppose that the effect of alcohol on the failing circulation or respiratory centre, if it had such action, was of this direct kind. He raised the question as to how far the good effects which alcohol might produce on the circulation and respiration were due, not to stimulation, but to weakening of excessive reflex excitability or of excessive inhibitions originating in the higher brain centres. A condition in which alcohol was habitually administered and credited with beneficial action, the syncope due to fright, pain, or excessive emotion, seemed to be one in which the heart and vaso-motor centre were subjected to severe central inhibition. If alcohol here assisted recovery, it would appear logical to suppose that it acted by weakening that excessive inhibition. Haldane's recent work seemed to point to an excessive reflex excitability of the respiratory centre as the cause of the rapid, shallow, ineffective respiration which impaired the oxygenation of the blood in the lungs. In a condition such as that seen in pneumonia, where restriction of the functional lung area, excessive excitation of the centre from the periphery, and abnormal reflex excitability of the centre itself might combine to impair the oxygenation of the blood, a sedative effect such as that of alcohol could be credited rationally with value. In so far as alcohol could assist in restoring a quiet, deep, effective respiration it ought to be of use. The blood would thus obtain the best oxygenation which the condition of the lung allowed, and the supply to a labouring heart, threatened with over-distension, of well-oxygenated blood could hardly fail to have a secondary restorative effect on the circulation. If this explanation of its action be accepted, there was no escape from the conclusion that alcohol was useless in many of the conditions in which it was still habitually employed. Among the several conditions which are probably confused under the vague title of shock it might be expected that those in which inhibitions were predominant would get some benefit from alcohol; in others in which a toxæmia causing peripheral stagnation of the blood was the predominant factor there seemed no likelihood of its having any good effect.

It would not be without value, he thought, if a protest were registered against the superstition with regard to alcohol as a sort of specific against infection, and against influenza in particular. There was no evidence in favour of its having a specific or prophylactic action against infection of any kind. Its admitted action as a superficial vaso-dilator seemed clearly to condemn its use as a preliminary to or during exposure to cold. After exposure, as an aid to the effect of heat externally applied, the same vaso-dilator action, combined with its mild narcotic effect, clearly indicated its possible usefulness.

Summary of the Position.

In summarising the position he said that we might safely credit alcohol with the power of acting as an emergency food or source of energy, as a mild sedative and narcotic, and a superficial vaso-dilator. The fact that it was the only available narcotic which at the same time had a significant food value, might be held to give it a special position. On the lines of these demonstrable actions he believed that such therapeutic action as it possessed could be explained, and on these lines he believed its inclusion in the Pharmacopœia could be defended, even in, or perhaps especially in, a country which effectively prohibited its popular consumption. It had probably a definite limited place in therapeutics, but its value had largely been discounted by the tendency to its indiscriminate and unnecessary use.

Energy Derived from Alcohol.

In the course of the discussion Dr. E. MELLANBY spoke of the value of alcohol as a food, and dealt with the question as to the amount of energy which could be supplied to the body by alcohol and the relation which alcohol bears to the other energy-producing foodstuffs. Atwater and Benedict had shown that a considerable amount of energy could be obtained from the combustion of alcohol in the body. He thought that the 25 per cent. mentioned by Dr. Dale was too low an estimate. One gramme of alcohol on combustion gave out seven calories of heat, thus comparing favourably with proteins and carbohydrates, which each yielded 4·1 calories of available energy. Practically all the alcohol was absorbed and oxidised, so that, disregarding its toxic action for the time being, it was seen that alcohol could supply a considerable quantity of energy to the body.

Dr. Mellanby then exhibited a series of curves illustrating the results of various experiments which he had carried out. The first showed the rate of entrance into and of disappearance from the blood of alcohol in the case of a dog, into the stomach of which 50 c.cm. of diluted absolute alcohol were introduced. This was completely oxidised at the end of 20 hours, or at the rate of 2·5 c.cm. of alcohol per hour, showing that 1·04 calories of heat per kilogramme body-weight per hour were supplied by the alcohol, representing 40 per cent. of the total heat lost during the period. Another curve showed the result of an experiment performed on a man weighing 70 kg., from which it could be calculated that he oxidised 10 c.cm. of alcohol per hour, the alcohol furnishing about 54 calories per hour, or, roughly speaking, 1300 calories per diem, representing about 40 per cent. of his total energy loss. From another curve it was seen that the rate of disappearance of alcohol from the blood, which almost certainly represented its rate of oxidation, did not depend, within fairly wide limits, on the amount present in the blood. In this experiment a dog received on different occasions doses of alcohol varying from 20 up to 55 c.cm. It had been shown that the depression in the respiratory quotient produced by alcohol was the same whether 30 or 45 c.cm. of alcohol were drunk, but this condition did not hold good for carbohydrates or fats. This, then, was the first great difference between alcohol and other foodstuffs—the rate of combustion was not as dependent on the amount consumed. Seeing that the man above mentioned, when at rest, oxidised 10 c.cm. of alcohol per hour, if the constant rate of oxidation held even with very low concentrations, it was only necessary to give doses of the order of 10 c.cm. per hour to such a man to get the maximum amount of energy in unit time. The smaller the dose the less the toxic action; it was thus possible to get out of alcohol the maximum amount of energy in unit time, and eliminate most of the acute effects due to its drug action.

Alcohol had no power of stimulating metabolism; in other words, it had no specific dynamic action. Although it supplied heat it did not make any more energy immediately available for the body. It simply conserved the stores of protein, fat, and carbohydrate in the body. This was another great difference between alcohol and other foodstuffs. Not only did alcohol not increase the amount of energy immediately available to the tissues, but in consequence of the heat loss following vaso-dilation of the skin vessels a fall in body temperature might follow. More especially would this be the case if the dose of alcohol was so great that it narcotised the neuro-muscular mechanism and thereby directly diminished the heat production.

Another point of difference between the oxidation of alcohol and of other energy-producing foodstuffs was seen when the effect of exercise and mechanical work was considered. Exercise only increased its rate of combustion to an extent comparable with other foodstuffs when lower concentrations were present in the body. With high concentrations in the case of dogs exercise had no apparent effect in increasing the rate of combustion. He raised the question as to whether a substance which only supplied energy and with no other favourable metabolic characters was necessarily always of value to the body. It did not appear to him quite certain that alcohol, given in such a way as to eliminate or reduce to a minimum its drug effect, would extend the life of a man dying of starvation. Taken with other food it would undoubtedly help to convert a negatively balanced diet into a positive one, thereby conserving the proteins, fats, and carbohydrates of the body; but when taken as the only source of energy, which might well happen in some diseases, it was not self-evident that existence would be prolonged by it. A starving man or animal did not die because of the lack of energy-bearing material in his body. Whether, by increasing the amount of these substances as the result of giving alcohol, life would be prolonged, was to him a matter of doubt.

Alcohol-oxygen Vapour.

Dr. W. H. WILLCOX spoke of the value of alcohol as administered in the form of alcohol-oxygen vapour, and referred to the experiments of Professor B. J. Collingwood and himself which were carried out in 1909–10. He was convinced of the value of the mixture in cases of cardiac failure, the good effect of which was not due to oxygen alone. Collingwood in 1909 gave poisonous doses of chloroform vapour to animals. The administration of oxygen and CO_2 restored the respiration, but the heart failure continued. Oxygen was then used alone after the respiration had improved, but for the cardiac failure following chloroform it was found that a mixture of alcohol and oxygen produced a marked stimulating effect, the blood pressure in many cases rapidly rising to normal. With regard to the method of administration in his own cases the oxygen, contained in a cylinder, was bubbled through absolute alcohol, and thence by tubing and a funnel to the patient. Special face-pieces had been found to be a source of discomfort to the patient.

Experiments showed that the optimal percentage of alcohol vapour was about 4 per cent. by volume, and this could be obtained by using absolute alcohol, and having the inlet tubes below the level of the alcohol.

It was found experimentally that the quicker the oxygen bubbled through the greater the percentage of alcohol in the mixture. Rectified spirit (90 per cent. alcohol) had been used, but gave off a smaller percentage of alcohol. Whisky (pre-war) and brandy gave off a still lower percentage, which was too low to be of real value. It was desirable that there should be from 3 to 5 per cent. of alcohol.

Regarding the therapeutic effects, he had not noticed any special effect on the normal person, but there was a marked beneficial effect on patients with severe cardiac failure. It was extremely valuable to tide a patient over a short period. It should be given continuously for about ten minutes or longer, then for five minutes every half hour or hour as indicated. He had used it for cases of pneumonia, pleurisy, various forms of morbus cordis, chloroform poisoning, asthma, and cardiac failure. He had also used it in cases of profound toxæmia, such as cholera and typhoid, when the patient was collapsed, with bluish colour and rapid and feeble pulse. The colour improved quickly (probably due to the oxygen), the rapid pulse was reduced by about 20 beats, and the blood pressure rose by about 30 mm. Hg. In considering the mode of action, he said that the method of administration was an important point. With inhalation the action was very rapid, as was the case with amyl nitrite in asthma. Only small doses of alcohol were given, and therefore no harmful effects on the liver or kidney were likely to result. With regard to its mode of action as a cardiac stimulant, he would suggest tentatively that (1) it minimised the inhibitory impulses from the vagus and nerve centres; (2) there was a direct stimulant effect of alcohol vapour on the heart.

A Digestive Stimulant.

Dr. R. HUTCHISON said that the therapeutic effects obtained from alcohol corresponded more closely with its pharmacological action than was usual with drugs. As regards some of its effects, there would be general agreement amongst clinicians: 1. Alcohol is undoubtedly a food, and is of special value for this purpose in diabetes and in prolonged fevers. 2. It is a digestive stimulant, and is often useful in cases of impaired appetite, gastric atony, and in convalescence. The form in which it is administered has, however, a great influence on its digestive value. It is also useful as a carminative in cases of severe flatulence. 3. Its effect in dilating superficial blood-vessels is of use in combating the effects of chill, as well as in rigors and in helping to reduce blood pressure during an attack of angina. 4. Its narcotic action is helpful in some case of insomnia, especially in old people, and in cases of delirium and restlessness in acute illness. The chief point of controversy would be as to whether alcohol could be regarded clinically as a cardiac stimulant. In cases of acute heart failure, as in syncope and fainting, its action in reflexly stimulating the heart was certainly of great use, but in his opinion there was no clear clinical evidence that it acted as a heart stimulant in cases of acute infection. On the other hand, by calming the nervous system, counteracting delirium, and promoting sleep it might benefit the heart in a case of prolonged illness indirectly, and he therefore made use of it in such circumstances, though he was guided in prescribing it rather by the state of the patient's nervous system than by the pulse. As to whether alcohol increased the patient's resistance there was considerable difference of opinion, but his own view was that there was some reason to believe that in septic infections, at least, it had some power in this direction.

Its Value in Anorexia and Vomiting.

Sir WILLIAM HALE WHITE said that therapeutically alcohol was of value as a food in certain cases of anorexia and vomiting which were met with in phthisis and cancer. It must never be given in functional anorexia and vomiting lest a habit should be formed. It was of use as a food during the starvation period of diabetes. When in acute fever, anorexia, vomiting, or indigestion were present, it was an excellent food, for it required no digestion, was easily absorbed, and had the inestimable advantage of making the patient feel comfortable and sending him to sleep. The disadvantages were that sometimes he complained of headache after it, and in a few cases its soporific effect was slight. During convalescence alcohol was of value, especially in the form of a glass of wine taken with a meal. The patient was weak and "all on edge," which meant that he was worried by peripheral stimuli which would not have affected him in good health. A glass of wine would annul these without doing appreciable harm; it would promote digestion and make the patient feel better and more comfortable. He had never known an alcohol habit formed from taking it during convalescence. The therapeutic value of the effect on the circulation was very difficult to estimate except when it was given in concentrated form in order to rouse a patient from a faint; its action was then entirely reflex from the mouth and stomach. At present little or no alcohol was given in pneumonia, but he did not think that the outlook in this disease was better or worse than it had been, nor was he convinced that it did harm or good to the circulation. Even if alcohol had a beneficial effect on the respiration, this function was unimportant in the treatment of acute fevers, for in these cases death was nearly always due to cardiac failure. He thought that the chief therapeutic value of alcohol was as a pleasant depressant peculiarly efficacious in inhibiting peripheral sensations, such as slight pain and discomfort, and by its slight cerebral depressant effect, so diminishing the trivial worries that bother the sick. As such in small doses it was useful to the convalescent, in larger doses to the patient acutely ill, making him feel more comfortable; in larger doses still it made him sleep. For these uses it had the great advantage of being easily and rapidly absorbed. There were two difficulties to surmount in a discussion of this sort—(1) it did not follow that the effect of the drug was the same in health as in disease, and its effect in disease was often very difficult to estimate; (2) no sick person took a mixture of pure alcohol and water. Perhaps the other bodies present in wines and spirits had their actions. Certainly they were believed to have, for it was considered that brandy was the best form of alcohol for diarrhœa, and that old brandy had superior therapeutic effects.

Alcohol in Diabetes.

Dr. O. LEYTON said that it was extremely difficult to draw any conclusion as to the effect of alcohol administered to cases in which it was thought that the heart would cease to work and death would ensue from that cause. At the present day we had no method of determining whether the heart was likely to stop beating, and several cases in which that termination had been feared had died from respiratory failure. In prolonged diseases, such as typhoid fever, alcohol might prove a most valuable adjunct to dextrose and other easily assimilable substances, but the tendency to administer food in short fevers was ill-advised if the patient did not crave for food, for most individuals could live upon their own tissues for many days without detriment. In diabetes it had been his custom to order alcohol as a foodstuff during the period of very meagre diet, to those patients who had been accustomed to take alcohol in the past. There seemed to be two advantages in this: first, the supply of a small amount of energy; and secondly, the patients were less irritable, pangs of hunger were more easily borne, and the patients seemed to be able to stand treatment better. The less alcohol the patient took as a luxury the better, but a large number of cases of diabetes mellitus had come under treatment in which the maximum diet which they could take represented about 20 calories per kilogramme, or rather less than half that which was thought to be necessary for the patient to be able to maintain life and energy. It was in those cases, in his opinion, that alcohol was essential.

Dr. Leyton then gave an account of a woman of about 20 years of age who had been under his observation for nearly three years. She weighed about 5 st. 6 lb., presented an appearance of great emaciation, and was found to have a tolerance of only: carbohydrate, 20 gr.; protein, 45 gr.; and fat, 60 gr. If any one of these were increased sugar appeared in the urine. Since the diet was so meagre it seemed to him hopeless to try to find one in which sugar in the blood was normal. This diet represented about 800 calories, or less than 25 calories per kilogramme. It was very unlikely that the patient would be able to enjoy her life on this diet, and he therefore added to it slowly and gradually 2 oz. of absolute alcohol daily. Absolute alcohol was chosen because the patient intensely disliked brandy, whisky, gin, or other alcoholic beverages. The absolute alcohol was ordered to be given well diluted and to be taken with meals, for by giving it with meals it was absorbed more slowly and was less likely to produce any excitement or somnolence. During the last year or so an improvement on dilution with water had been made by incorporating the alcohol into a jelly made with agar and flavoured with citric acid, oil of lemon, and saccharin. This jelly without alcohol was, as far as he knew, of no nutritive value, but tended to satisfy hunger. From it the alcohol diffused out comparatively slowly and was slowly absorbed, so that in many ways it was an ideal method of administering it. The addition of 2 oz. of alcohol to the diet increased its value by 300 calories, so that the energy of the diet was increased to 30 calories per kilogramme, which experience had shown was sufficient to allow an individual to take exercise and gain weight extremely slowly. This patient was now able to walk six miles daily. He had come to the conclusion that alcohol was a necessity in some of the more advanced cases of diabetes mellitus, and he had on record patients who had maintained their weight whilst taking alcohol, but who had lost weight after they had stopped taking it, the diet having been maintained constant in every other respect. In diabetes the metabolism was extremely unstable, and care must be taken in drawing conclusions. When a patient was on a small diet and sugar free a slight disturbance, such as inoculation with a vaccine for influenza, streptococci and pneumonia, might lead to the appearance of sugar in the urine, and any infection or even emotional disturbance might produce the same effect.

Professor W. DIXON thought that, with regard to alcohol, the question of the definition of the word "food" was academical. If other foodstuffs were spared it came to the same thing. Hamill had found that the isolated heart could oxidise alcohol, and that alcohol could be substituted to some extent for glucose in Ringer's solution. Not only was alcohol absorbed with ease from the stomach and intestines, but it facilitated the absorption of other foodstuffs given with it.

Dr. W. LANGDON BROWN said that opinions on the therapeutic value of alcohol had been very much governed by tradition in the past, and he thought the discussion that afternoon proved that tradition still held sway, so that it was difficult for clinicians always to give definite ground for the faith that was in them on this subject. There were four types of cases where he felt alcohol could be of therapeutic service: 1. In the fasting treatment of diabetes, where energy could be obtained from alcohol and the calorie value raised to a more reasonable figure. 2. Dilute alcohol was found by Bickel to be one of the direct chemical stimulants of gastric juice, the others being meat extracts, condiments, and aerated waters. 3. He believed, with the President, that alcohol was often very useful in removing nervous inhibition, and thus contributed to the patient's comfort. 4. Like Dr. Willcox, he thought that the administration of oxygen over brandy contributed to the recovery of some cases of pneumonia. But the fallacy inherent in all attempts at exact estimate of therapeutic conclusions on clinical grounds was the absence of controls.

Effects in Children.

Dr. M. ESTHER HARDING said that children were valuable in estimating the effects of alcohol, because the æsthetic effects might be entirely discounted. In the case of children the uses of the drug fell under the same headings as in adults. 1. In respiratory embarrassment, especially the rapid, shallow, inefficient breathing of broncho-pneumonia, alcohol quieted the respiration and so made it more efficient. It was true that the indication for the use of alcohol was commencing failure of the right heart, but the effect of the drug was not to flog the already over-burdened heart, but to relieve it of some of its intolerable burden by slowing the respiration and improving the oxygenation of the blood. 2. Alcohol was, in her opinion, the most valuable sedative and hypnotic drug we possessed for infants and young children. 3. As a food in cases where no ordinary diet could be taken: (*a*) in milk intolerance of marasmic infants alcohol would sometimes tide a patient over a few days till milk or whey tolerance could be re-established; (*b*) in the persistent late vomiting which killed so many patients after severe diphtheria. She had kept a child alive on more than one occasion under such circumstances on saline, brandy, and sugar, given by the stomach, for three weeks. A word of warning on the danger of the persistent use of alcohol in young children was hardly needed, but it was wise to remember that small doses of spirit given to an infant over a period of weeks might easily result in damage to the liver.

SECTION OF OPHTHALMOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 4th, under the presidency of Mr. W. T. HOLMES SPICER.

Mr. G. WINFIELD ROLL showed a patient, aged 27, with New-formed Vessels on the Iris, the condition having existed since infancy. In the right eye were a number of vessels on the front of the iris, radiating from the periphery to the margin of the pupil. The eye was blind and somewhat disorganised, and as it had recently become painful the patient was anxious to have it removed. Her good eye had two areas of coloboma in the fundus, the one below the disc looking like a congenital coloboma of the choroid. A floating band came forward to the back of the lens, but it could not be traced to its attachment. The eye was highly astigmatic.

Mr. TREACHER COLLINS's view was that it was a persistence of the fœtal vascular system, and he believed removal of the eye would disclose a patent central hyaloid artery.

The PRESIDENT referred to several similar cases which he had seen. One was an old iritis and cyclitis case, and this was followed by increased tension. He wondered at the time how far the prolonged use of eserine had increased the growth of the vessels.

Mr. HUGH THOMPSON showed a patient with Macular Detachment of Retina, probably due to a new growth. There had been a regularly increasing grey detachment, but no increased tension. The site, he believed, was an uncommon one for new growth.

Pulsating Exophthalmos.

Mr. H. GRIMSDALE described a case of Pulsating Exophthalmos, which Mr. Frost showed in 1883. Sixty-five years ago the drumming sound in his head was set up by being run over by an empty van. The left eye was prominent, but he never noticed any diplopia. Mr. Grimsdale raised the question whether the statement so frequently made in books, and in the literature generally, that paresis of the third nerve was the prominent feature in these cases, was correct. In the few cases of it he had seen it was the sixth nerve which was most markedly affected. This man had complete paresis of both sixth nerves. It was what would naturally be expected, as the sixth was within the area of pressure.

Mr. C. HIGGENS spoke of two cases which started with the onset of labour. They recovered in a few months without special treatment.

Mr. J. H. FISHER agreed that the sixth was the nerve most likely to be involved in these cases, and entered into the anatomical reasons for it.

Gunshot Wound of Occipital Lobes.

Mr. NORMAN B. FLEMING showed a case of gunshot wound implicating both occipital lobes, the patient having been blind for four days after the receipt of the injury. Fragments of bone and metal were removed at the casualty clearing station. His present complaint was of headaches, giddiness, slight deafness on the right side, and some loss of sight, but central vision is acute. The fields show a sharply defined hemianopia below in each eye, with a considerable reduction of the peripheral part of the upper field.

Mr. **FISHER** spoke of a similar case which he saw in the Boer War and detailed the findings. He considered there was direct lacerated damage to one half and concussion effects on the other, probably causing œdema and punctiform hæmorrhages.

Mr. N. **BISHOP HARMAN** showed a case of new growth in the eye, which was becoming increasingly painful. The general view was that it was a glioma and should be removed.

THE RADICAL CURE OF GONORRHŒAL IRITIS.

Mr. S. H. **BROWNING**, bacteriologist to the Royal London Ophthalmic and All Saints' Hospitals, contributed a paper on this subject. He said that gonorrhœal iritis, being a late sequela of gonorrhœa, was not usually seen at first hand by venereal disease specialists, hence it was often not treated as a local affection. He contended that very few, if any, cases of gonorrhœal iritis ought to occur, and certainly there should not be recurrent cases if proper treatment were carried out. His object in reading the paper was to show that by thorough treatment of the genito-urinary tract in subjects of gonorrhœa the iritis would be permanently cured. He regarded gonorrhœal iritis as a toxic condition, that it was not due to the actual presence in the eye of the gonococcus. In only one case had the organism been isolated from the eye itself, and that was in Sidler-Huguenin's case, in which it was discovered in the blood-stained exudate from the anterior chamber of a case of gonorrhœal septicæmia. The author had himself tried many times to cultivate the organism from the exudate within a few seconds of it being drawn off, but had always failed. In these cases there was usually a history of gonorrhœa some years previously; he had never seen a case of iritis during the acute stage of urethritis, and others had confirmed this, on the observation of many thousands of cases. There is, in these cases, a specific reaction to gonorrhœal vaccines. It is not invariably associated with gonorrhœal rheumatism. There is a recurrence of the iritis, or an exacerbation of the symptoms after prostatic and vesicular massage, probably on account of toxins being thereby liberated into the blood-stream. The diagnosis is also helped by eliminating such sources of infection as pyorrhœa, septic tonsils, ear trouble, cystitis, and alimentary affections. The complement-fixation test had not given reliable results in his hands.

He considered treatment under two heads: preventive and radical. The first of these rested with those who saw such cases early; he laid great stress on the need for thoroughness at the hands of a genito-urinary specialist, for in that case he believed there would be no such condition as gonorrhœal iritis. Though vaccines did not materially shorten the acute stage of the disease, complications and sequelæ were largely prevented by their use. The radical treatment should consist of (1) immediate treatment by the ophthalmic surgeon; (2) the immediate use of vaccines; (3) continued treatment by vaccines and prostatic and vesicular massage, with, if necessary, treatment of the urethra. While an autogenous vaccine is being prepared, he urged the use of suitable doses of a reliable mixed vaccine. Some of the loss of repute of vaccine therapy in this connexion he attributed to the haphazard use of commercial vaccines. The proper dose of vaccine varied with each patient; his own range of experience varied between 5 millions and 500 millions. Vaccine therapy was no more than an aid to medical and surgical treatment; it was not a substitute.

Mr. Browning then proceeded to outline the proper method of carrying out massage of the prostate and vesicles. He did not think iritis was often due to other bacteria found after massage, such as staphylococci, *B. coli*, diphtheroids, &c. He had not met with a case of gonorrhœal iritis in a female. He narrated the leading facts in the histories of ten cases which he had carefully followed out, and which bore out his contentions; he had notes of 47 cases of the condition.

Discussion.

Mr. C. H. **MILLS** considered that no prostatic or vesical massage should be carried out until the acute stage of the iritis had subsided, nor should vaccine treatment be commenced until then. Massage resulted in a large dose of the toxin being liberated into the blood-stream. Any source of co-existing sepsis in the patient should be carefully searched for. A patient with both gonorrhœa and pyorrhœa was very likely to have joint trouble or other metastases. All cases of iritis in people who had a septic focus in the prostate or vesicles were not necessarily of gonorrhœal origin; he believed that in many such the original gonococcal activity had died out, and the lesion was perpetuated by a mixed infection on the original site of damage. He referred to the work of Colonel Young, of the American army, in his effort to trace a connexion between rheumatoid arthritis and chronic vesiculitis. In the majority of cases of vesicular trouble Colonel Young had isolated a streptococcus. Mr. Mills said he considered that 80 per cent. of the adult population of towns had had gonorrhœa. When the iritis occurred not more than three or four years after the gonorrhœa the cure was very hopeful, as the patient was usually capable of a generous production of antibodies.

Mr. **HIGGENS** narrated the histories of two long-standing cases which had had many recurrences of iritis over a number of years. Only one had vaccines, but in both the attacks ceased at about the sixtieth year, which probably meant that the stock of toxin had been used up and no further dose was acquired.

Mr. **BISHOP HARMAN** raised the question of carriers of the disease, and asked whether the fact that the disease was not conveyed to another after massage had been practised meant that after this process the gonococcus was sterile.

Mr. C. B. **GOULDEN** challenged Mr. Browning's contention that gonorrhœal iritis was not due to the actual presence of the organism in the eye.

Mr. WM. **LANG** discussed the justifiability of slitting up the vas deferens for the purpose of injecting argyrol.

Mr. **WHITING** spoke of the definite negative phase which followed a dose of vaccine, and was sometimes alarming for a time. But, unlike the similar phase in tuberculosis following the use of tuberculin, he had not seen a disastrous result from it. A marked positive phase followed, and with the continued use of the vaccine and the ordinary eye treatment for the iritis, the case progressed satisfactorily. He had not seen bad results follow the use of vaccine in the acute stage of iritis, at least for more than 24 hours.

Mr. **FISHER** asked as to the respective rôles played by vaccines and by prostatic and vesicular massage. If both were really necessary they should be carried out hand in hand.

Mr. **MILLS**, in the course of his reply, said that in nearly 100 per cent. of cases the posterior urethra was infected by the twelfth day, and it occurred especially early when syringes were being used by the patient himself. He had seen acute prostatic involvement within a month of the primary infection. Gonococci might be encysted, and in that way be carried about for years, and apparently without infecting others. Surgical exposure of the vas in this condition he regarded as a very drastic procedure and never necessary. He recommended distension of the bladder with 1 in 4000 permanganate, so that it could deal with organisms entering the viscus during or following the massage. Investigations on the subject of "protein shock" had shown the capacity of foreign protein to awaken the tissues out of a habitual lethargy and enable them to deal successfully with a microbic invasion.

Mr. **BROWNING** also replied, pointing out that patients at once began to improve as soon as they got over the negative phase; the iris went on to recovery in an extraordinary way. He thought gonococcal vaccine should be used, not necessarily sufficient to produce a severe reaction, but to stimulate the production of antibodies.

SECTION OF LARYNGOLOGY.

EXHIBITION OF CASES AND SPECIMENS.

A MEETING of this section of the Royal Society of Medicine was held on Feb. 6th, Mr. MARK HOVELL in the chair.

Naso-pharyngeal Tumour.

Mr. CHARLES CUTHBERT showed a Naso-pharyngeal Tumour which he had removed by lateral rhinotomy. The patient, a man aged 30, had intense headache and dyspnœa, and a tumour protruded from the right anterior naris, and occupied, too, the left naris, and projected into the naso-pharynx. There had been several severe hæmorrhages. The laryngotomy was performed under novocain anæsthesia, followed by a general anæsthetic through the laryngotomy tube, the pharynx being plugged. The modified Moure's operation secured good exposure of the nasal cavities. Bleeding was controlled by Crile's clamps on both external carotids. Though an extension of the growth had penetrated into the frontal cavity of the skull the dura mater appeared not to have been injured, and no cerebro-spinal fluid escaped. The microscopist reported the tumour to be an adeno-fibro-myxoma.

Sir WILLIAM MILLIGAN referred to the value of Kuhn's peroral intubation tubes for intratracheal anæsthesia in these cases.

Mr. H. TILLEY asked as to the actual origin of the tumour. He recommended the turning up of the cheek and removing both ascending maxillary processes, which gave a good view cf the area of operation, and rendered unnecessary the procedure adopted in this case; moreover it did not expose either external carotid.

Mr. W. STUART-LOW considered that the route through the antrum was a very good one in these cases, and it was not his practice to perform laryngotomy.

Mr. E. D. DAVIS congratulated Mr. Cuthbert on having ligatured both external carotids, as tying one only in the case of such a large growth he had found ineffective.

Dr. W. HILL pointed out that the carotids were only clamped in this case, and he thought there was a wider field of usefulness for these clamps.

Dr. P. WATSON-WILLIAMS hoped it would not go forth that ligature of only one external carotid was of no use; he had found a marked inhibiting effect in malignant growths of one tonsil from the ligature of one carotid.

Mr. W. DOUGLAS HARMER said in some of these cases the tumour proved to be fibro-angioma, a very vascular kind of tumour. Some of them had been fatal solely on account of the furious hæmorrhage. He thought Mr. Cuthbert had adopted the safer procedure. The method of approach he did not regard as nearly so important as securing a thoroughly good exposure.

Mr. C. W. HOPE referred to a case of angeio-fibroma in which the severity of the bleeding compelled a cessation of the operation for a fortnight, and when the tumour was examined microscopically it was found to have enormous blood spaces.

Dr. IRWIN MOORE alluded to the rarity of adenomatous or mixed adenomatous growths of the nares, and considered that this was a nasal growth arising from the middle turbinal or ethmoid region, and as such should be classified and described as a nasal growth extending into the naso-pharynx. This was important for the correct indexing of recorded cases. In the case of benign growths there was not usually much hæmorrhage, but he thought Mr. Cuthbert had kept on the safe side in preparing for such an emergency.

Sir STCLAIR THOMSON referred to the advantages of Moure's operation and exhibited drawings showing the satisfactory exposure of the growth obtained. He also referred to two cases of malignant growths he had operated upon by this method, one patient being alive and well six years, and the other three years, after operation.

Mr. CUTHBERT also showed a youth of 19, on whom thyroidectomy had been done for exophthalmic goitre. During the operation the pulse-rate varied between 180 and 200. He got well, and, until he was killed in France, was very active.

Pharyngeal Diverticuli.

Mr. S. HORACE LAW reported two interesting cases of Pharyngeal Diverticuli, one associated with the impaction of a foreign body. The outstanding feature of both cases was the increased salivation and the difficulty of disposing of the fluid. The hyper-secretion became normal in the one case after removal of the foreign body, and in the other after the operation of removal of the pouch. The ages of the patients were 53 and 70.

Dr. W. H. KELSON called attention to the importance in the removal of these pouches of passing a guide either before or immediately after giving the anæsthetic, because these patients were often in an exhausted condition, and time became important.

Dr. HILL spoke of the extreme thinness of the wall in some of these pouch cases, and hence the danger of rupture by the passage of a tube.

Dr. IRWIN MOORE advised coöperation between the general physician and the laryngologist, which would result in these cases being seen and treated much earlier.

Dr. J. DUNDAS GRANT described similar cases, and spoke of the importance of X ray examinations.

Mr. G. H. LAWSON WHALE showed a case of Rhinoplasty in a man who had been severely wounded in France, and received the congratulations of several members on his result.

Malignant Disease of the Upper Jaw.

Mr. HOPE showed a case of Malignant Disease of the Upper Jaw, for which lateral rhinotomy was performed. The growth was found to be epithelioma, and a section was shown. It started apparently in the ethmoid region, involving ethmoid, antrum, bony orbital floor, malar bone; and soft tissues in the pterygoid region. Hæmorrhage was practically nil, and progress uninterrupted. Radium had been applied since, and seven months later there was no sign of recurrence.

Dr. D. R. PATERSON thought it important to obtain permission from the patient before the operation to sacrifice the eye, if that proved necessary in order to remove the whole disease.

Laryngeal Case for Diagnosis.

Dr. ANDREW WYLIE showed a laryngeal case for diagnosis, which Sir WILLIAM MILLIGAN believed to be a post-cricoidal carcinoma, and with that view Mr. TILLEY agreed.

Dr. PATERSON said the case illustrated the type of condition he drew attention to in an address before the summer congress of the section—namely, a long history of dysphagia, with smooth glossy tongue and cracks in the lips. Dr. Thomas Guthrie, of Liverpool, had since declared this sequence to be quite common.

Actinomycosis of Tonsil.

Dr. POTTER exhibited a case of Actinomycosis of the Tonsil.

Major PARRY said it had been successively regarded as syphilis, diphtheria, and Vincent's angina, and some thought it might be epitheliomatous. The whole tonsil was found to be infiltrated with the parasite. He discussed the subject from the standpoint of the pathologist.

Copper Alamine in Lingual Cancer.

Dr. JAMES DONELAN again showed a man, aged 65, whose lingual cancer appeared to have been checked by treatment with copper alamine.

Dr. DAN MCKENZIE spoke of the cleaning-up influence of the copper alamine and its freeing of the area from septic material. This was probably a large part of the apparent benefit, and the same could be said of diathermy, which had a similar cleansing effect, and cancerous progress seemed to be much slower in consequence.

Mr. DOUGLAS HARMER agreed that cancer did not progress so fast in clean surroundings.

Atrophic Catarrh of Trachea.

Mr. L. COLLEDGE showed a patient with Atrophic Catarrh of the Trachea. Wassermann reaction was negative.

Mr. STUART-LOW urged that the man should leave his dusty warehouse occupation.

Mr. J. F. O'MALLEY recommended small doses of vinum antimonialis, and Dr. IRWIN MOORE suggested ammonium chloride in solution, applied by means of a powerful atomiser.

The Galvano-cautery in Laryngo-fissure.

Mr. G. W. DAWSON showed a patient on whom laryngo-fissure was performed four months ago. The galvano-cautery was applied for the troublesome bleeding which occurred during operation.

Mr. TILLEY and Dr. IRWIN MOORE objected to the use of the galvano-cautery to check hæmorrhage in laryngo-fissure owing to the sloughing which ensued and the danger of secondary hæmorrhage.

? Papilloma of Larynx.

Mr. H. BUCKLAND JONES showed what he regarded as probably a Papilloma of the Larynx. He invited opinions as to its malignancy.

Sir STCLAIR THOMSON referred to the difficulty of diagnosis in such conditions, even though a piece were removed for the purpose. This seemed well defined and limited for a simple papilloma.

Mr. LAWSON WHALE mentioned a case in which a well-known laryngological pathologist could not be sure of the diagnosis. The growth was removed and proved to be malignant.

Dr. KELSON showed a case of Ulceration of Pharynx and Larynx. There was no history of syphilis, and no tubercle bacilli were found. The left arytenoid and left ventricular band were markedly œdematous.

THE International Society known as "Pneumothorax Artificialis" has been revived. It was founded at the Rome Tuberculosis Congress to form a link between those in all countries practising nitrogen replacements, so as to ensure continuity of treatment on the patient's change of residence. The secretary is Professor U. Carpi, of Lugano.

RÉUNION OBSTETRICALE ET GYNÉCOLOGIQUE DE MONTPELLIER.—At Montpellier the sittings of the Obstetrical Society have now been regularly resumed, and a number of interesting communications were read at two recent meetings. At the first M. Guerin Valnale described a case of Pregnancy with Inoperable Carcinoma of the Cervix. Labour was premature, a child weighing less than 1600 g. was delivered by Cæsarean section. Subtotal hysterectomy was then done, and there was marked arrest of the rate of growth of the tumour for three months afterwards. In the discussion which followed M. Vallois said he had practised in similar cases Cæsarean section followed by Porro's operation.—M. Vallois described a case of Convulsive Movements in the Left Arm in a baby a few days after its delivery with forceps. A portion of the right parietal bone was removed and a collection of blood evacuated after opening the dura mater. Complete recovery followed the operation.—M. de Rouville read the notes of a case of Tubal Abortion with the formation of a hæmatocele between the uterus and the bladder. Firm adhesions of the lower border of the great omentum to the posterior aspect of the left appendages determined the rare situation of the blood collection. There was no trace of blood in Douglas's pouch.—M. de Rouville also described a case of Complete Inversion of the Vagina following vaginal hysterectomy for complete prolapse of the uterus. He performed total excision of the vagina and restored the perineum in layers. The operator discussed the case and the methods of treatment.

At the second meeting M. de Rouville and M. J. Cohen described two cases of Ovarian Grafting, with the results that followed. In the first case both breasts increased in size, and became painful at the menstrual periods. The latter, which were quite regular at first, became irregular later, and metrorrhagia also occurred. Nervous symptoms were less intense. The grafts were removed on account of the hæmorrhage, with the result that all bleeding ceased immediately. Microscopic section of the grafts showed them to be active but degenerating. In the second case menstruation was quite regular three months after the operation and remained so for six months. No breast changes were observed. There was excellent health for a year, followed by pains in the left iliac fossa, which necessitated a second operation five and a half years after the first. Adhesions were freed round the left appendages, and subtotal hysterectomy was done. Macroscopic and microscopic section of the uterus showed "sclerotic and atrophic" changes; thus it was concluded that menstruation after grafting was due to the grafts and not to supernumerary ovaries. In each case the grafts were autogenous, and was placed in the subcutaneous tissue of the abdominal wall.

Reviews and Notices of Books.

DISEASES OF WOMEN.

By Ten Teachers. Under the direction of COMYNS BERKELEY, M.A., M.D., F.R.C.P., Obstetric and Gynæcological Surgeon to the Middlesex Hospital. Edited by COMYNS BERKELEY, H. RUSSELL ANDREWS, and J. S. FAIRBAIRN. London: Edward Arnold. 1919. Pp. 650. 30*s*.

THIS is a companion to the book on Midwifery by the same Ten Teachers. As the authors point out in the preface, there is more room for diversity of opinion in an account of the diseases of women than there is in a text-book on midwifery, and consequently it has been more difficult to give a collective opinion in some parts of this book. An attempt has been made to approach the subject from the point of view of State medicine, and to develop the preventive attitude in the mind of the student. With this object a précis of the report of the Royal Commission on Venereal Disease has been included. A chapter on the part played by the psychological factor in the ætiology of pelvic disease has also been introduced. The book forms a sound guide to the student on diseases of women, and will no doubt be as widely read as the companion volume on Midwifery.

A special section is devoted to the main symptoms associated with diseases of the pelvic organs, and in this the chapters dealing with dysmenorrhœa and abdomino-pelvic pain are excellent. On p. 169 there is an interesting diagrammatic drawing of the manner in which shortening of the utero-sacral ligaments is supposed to produce acquired anteflexion; we should like to ask the authors if any one of them has ever met with the condition delineated in the drawing. It is a curious fact that when the abdomen is opened in cases of old chronic pelvic cellulitis this condition is not met with, and we very much doubt whether anteflexion is ever produced in this way. Has it been seen either in the post-mortem room or on the operating table? The chapter on endometritis is on modern lines, and should give the student a good idea of what is meant when this term is employed. The authors believe that there is such a condition as chronic endometritis, and that the thickening of the endometrium, associated with it, may be taken to represent the overgrowth moiety of a past chronic inflammatory process. They do not believe that the thickening in the great majority of these cases is due to overgrowth from chronic congestion. In the chapter on chronic metritis they distinguish clearly between the two types, one corresponding to subinvolution and the other to a pure hypertrophy of all the elements of the uterine wall. We notice a slight error on p. 224—"symphysis pubis" should, of course, be "pelvic brim"; the normal uterus is never below the level of the symphysis pubis, using these words, as they should be used, in their proper anatomical sense.

In the treatment of retroflexion of the uterus after delivery the recommendation is made to introduce a ring pessary; we suggest that a Hodge pessary acts better in these cases, and has the advantage that it does not stretch the vagina so much, and therefore has less tendency to produce subinvolution of that canal. There is a very good discussion on the relative advantages of early and late operations in cases of inflammation of the appendages, and both views are well presented. The treatment of a uretero-vaginal fistula is not of much importance from the student's point of view, but we doubt the statement that the best operation is to open the abdomen and to attempt to implant the cut ureter in the bladder; a number of these cases have now been cured by plastic operations on the vagina, and this should have been mentioned. We cannot agree with the statement that treatment with radium is not so successful as X rays in relieving the symptoms due to fibroid tumours; we believe it probable that in the future treatment with radium will play a larger part in the cure of the hæmorrhage due to fibroids.

The chapters dealing with cancer of the body and neck of the uterus are particularly good, and should be most helpful to the student. The authors prefer the term cystic embryoma to that of dermoids of the ovary, and favour the view of their origin by fertilisation at a later date of primordial ova in the ovary of the developing embryo (epi-embryogenesis). They might have added that this suggestion explains the frequency of ovarian dermoids and the great rarity of dermoids within the testis. The chapter on neurasthenia in association with diseases of the pelvic organs will help the student to understand how often in minor pelvic ailments it is more important to treat the patient than her pelvic organs. The sections describing the various operative procedures are sufficiently full and the illustrations are clear.

This is a good book, reflecting great credit on those who have contributed to it and supervised it.

THE PRINCIPLES OF GYNÆCOLOGY.

By W. BLAIR BELL, B.S., M.D. Lond., Gynæcological Surgeon, Royal Infirmary, Liverpool, &c. Third edition. London: Baillière, Tindall and Cox. 1919. Pp. 660. 38*s*.

IN the preparation of this third edition Dr. Blair Bell has rewritten a considerable portion and added much material and many new illustrations. The pathological arrangement of the book has been retained, and the author has wisely not attempted to describe the many variations in technique of different surgeons in the section on operative procedures. The appearance of a third edition of this text-book within nine years proves that it has met with appreciation.

The first section dealing with the evolution, development, and anatomy of the female pelvic organs is good; it is, indeed, in our opinion, the best description of this subject to be found in any English text-book of gynæcology. It is interesting to note that the author does not believe that the so-called vascular caruncle is an angioma; rather he thinks it is an infected papilloma, containing generally no adenomatous tissue. An erosion of the cervix is regarded as an adenoma, and is recommended to be treated by excision or scraping; in the same way the condition called in some text-books chronic hypertrophy of the endometrium and in others endometritis, Dr. Blair Bell terms a diffuse adenoma of the endometrium, rejecting the term endometritis altogether. It is a pity that this condition should be described in so varying a manner by the authors of most of the popular text-books, so that in one book the student is taught to look on these conditions as due merely to an abnormal persistence of the normal ante-menstrual congestion, in another that they indicate a condition of chronic inflammation, while in a third they are described as innocent neoplasms of the genital tract. Little wonder that the average student is very confused on the subject. In the surgical treatment of fibromyomata of the uterus the author is in favour of supravaginal hysterectomy, with the retention of the ovaries and sufficient endometrium to ensure subsequent menstruation. It is unfortunate that the tumours generally known as adenomyomata and adenofibromyomata are described in this work as endometriomyomata and endometriofibromyomata, although as they are relatively unimportant it is not of much moment.

In considering the prophylaxis of carcinoma of the cervix great stress is laid upon the importance of repairing lacerations of the cervix and of adequately treating chronic cervicitis, the two most powerful predisposing factors in the development of these growths. We are glad to see that Dr. Blair Bell makes a plea for greater simplicity in the classification of carcinoma of the body of the uterus. We quite agree that the minute distinctions made by some authors are unnecessary and misleading to the student. The section dealing with gynæcological operative procedures is sufficient and well illustrated, as, indeed, is the book as a whole.

This is a distinctly good and well written work, bearing the imprint of the author's personality, and therefore much more interesting to read than many colourless compilations.

FIELD AMBULANCE ORGANISATION AND ADMINISTRATION.

By JAMES HARDIE NEIL, Lieutenant-Colonel, N.Z.M.C. London: H. K. Lewis and Co., Ltd. 1919. Pp. 125. 4*s*. 6*d*.

THIS little book consists of a condensation and extradition of matters relating to field ambulance management from official manuals and orders with addition of a great deal of most valuable suggestions and scheduled routine duties and regulations based on extensive personal experience in the field. Colonel Hardie Neil's name was known up and down the line wherever the New Zealand Division wandered, and his keenness and energy in everything that appertained to the maintenance of a healthy mind in a healthy body was well known. It is difficult to imagine how his activities as an efficient commanding officer, captain of a doughty cricket XI., and manager of a concert party could have permitted sufficient time for the collection and arrangement of the large quantity of valuable material that is contained in this little book. No single item of field ambulance work, whether in the line or at rest, appears to have been overlooked.

The author is to be congratulated on the publication of a small book, entirely free from padding, and full of information that cannot fail to be of great assistance to all field ambulance officers. Many will feel sorry that it was not available in the days when they had real need of such a vade mecum.

THE LETTERS OF A WIDOWED PHYSICIAN TO HIS DAUGHTER.

London: Baillière, Tindall, and Cox. 1920. Pp. 64. 2*s*. 6*d*. net.

THIS is an excellent little book, comprising within its 64 pages more common-sense than is found in many more pretentious treatises. It is published in four separate sections, which, says the author, can be handed out to their recipients at the proper ages—i.e., at puberty (12½ years), at maturity (18 years), at marriage, and at motherhood. The information and advice given are very plain-spoken, but withal duly reticent and dignified, and the only exception that we can find to take is that as the girl to whom the letters are addressed is advised by the author "to let your sisters know about it"—i.e., the oncoming of menstruation, we should have thought that her father need not have told her so much about it, unless she were an eldest or an only daughter. However, perhaps this is hypercriticism, and the book as a whole is admirable. Especially so is the section on matrimony, for even nowadays many a girl plunges into matrimony with only the haziest ideas of what the estate implies, with the consequence that difficulties arise which sometimes lead to two lives being ruined. Against such tragedies as these this little book might be a safeguard.

THE SOUL IN SUFFERING.

A Practical Application of Spiritual Truths. By ROBERT S. CARROLL, M.D. New York: The Macmillan Company. 1919. Pp. 242. 8*s*. 6*d*.

WHO first gave this opinion of a book, for it has many attributions: "Those who like this kind of book will find this book the kind of thing they like"? We can say the same of Dr. Carroll's work. He tells us that it "stands for medical ideals reaching out to Christian ideals, that one of the greatest problems of human existence—the problem of suffering, which through the ages has been so pitiably solved by the many—may be a bit more worthily met by all mankind." The problem of suffering is indeed one which is a great mystery, and one which so far has not yet been solved, and we cannot see that Dr. Carroll brings any light to bear on the difficulties. Platitudinous truisms, such as that most elderly people eat too much, that work is better than idleness, that a merely material life is not, or should not be, the only aim of humanity, are things to be remembered, but they do not go far towards helping the suffering soul.

SYPHILIS IN CHILDHOOD.

By LEONARD FINLAY, M.D. London: Henry Frowde and Hodder and Stoughton. 1919. Pp. 154. 8*s.* 6*d.*

THE author supplies an excellent and up-to-date survey of the lesions commonly seen in syphilitic children. Although primarily intended for those occupied with the clinical manifestations of syphilis, Dr. Finlay has not neglected to touch on such interesting topics as infection of the child in the absence of disease of the mother. It is impossible, in the author's opinion, to give a definite answer one way or the other to the question of paternal syphilis. More information is required before a decision on this point can be arrived at. At the same time it must be admitted that some clinical histories—e.g., those referring to women becoming pregnant in turn to syphilitic and non-syphilitic men, suggest that infection of the child may sometimes occur in the absence of infection of the mother. The question is of great interest, but one concerning which it is extremely difficult to obtain reliable information.

After describing the various lesions encountered amongst syphilitic children, the author discusses the relation of this disease to marasmus, the splenic anæmia of infancy, and Mongolian idiocy. In his experience the connexion between syphilis and the latter conditions is very doubtful. The author employs for the administration of salvarsan to infants the technique described by Norgerrall, preferring injection into the veins of the scalp to intramuscular medication. He rightly emphasises the importance and efficacy of antenatal treatment, and agrees with all those who have any experience in this matter as to the extremely satisfactory results thereby obtained.

The book is well illustrated, and contains some excellent reproductions of radiograms. The coloured plates are equally good. We recommend the book to all engaged in child welfare and in combating venereal disease.

LEHRBUCH DER PHYSIOLOGIE DES MENSCHEN.

Herausgegeben von N. ZUNTZ und A. LOEWY in Berlin. Leipzig: F. C. W. Vogel. 1920. Mit 302 Abbildungen und 3 Tafeln. Dritte verbesserte Auflage. Pp. 789. M.38.

THE first edition was published in 1909, and of the original collaborators three have since died—Professors Nagel, Schenk, and Langendorff. Professor Verworn (Bonn) writes a short chapter on the lines of his "General Physiology." The chemical constitution of the body and the morphology and chemistry of the blood on the usual lines are supplied by Professor J. Müller, of Dusseldorf; the general physiology of muscle and nerve by O. Weiss, of Königsberg; the central nervous system by the veteran, Professor Sigm. Exner, of Vienna. Other chapters on the various branches of physiology are each supplied by a specialist.

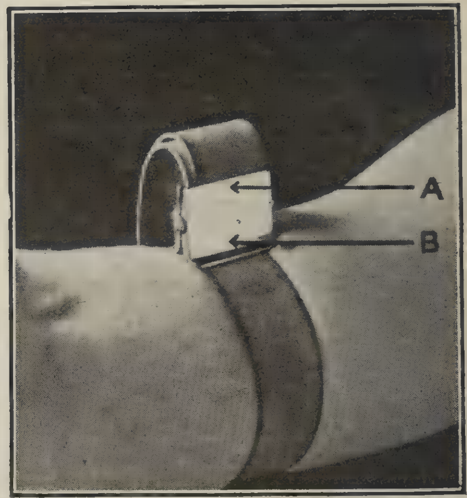
The amount of information of a purely physiological character—for there is but little histology—is very extensive, more especially when it is noted that the size of the page is relatively large, while there is a considerable percentage of small type used. Taken as a whole, this text-book will be found useful for reference, but the average student, German or other, will most likely be content with the large text or a part thereof. Exner's article on the central nervous system would have been improved by the introduction of a few more diagrams, more especially to elucidate conduction in the cord. Hypnosis and allied subjects receive more attention than in English text-books. The chapters on the senses, by Dr. Von Kries, are excellent. Some of the more recent work by English investigators does not seem to have found its way into several sections—for instance, into the article on the circulation, nor could we find much on aviation and the effects of high altitudes in this regard. The chapter on digestion is comprehensive. One of the best articles seems to us that by Metzner on Endocrine Glands and Internal Secretions. Whatever is said about vitamines in the text, this word is not to be found in the index. Perhaps the secretion of urine might have been more fully dealt with, and the same remark applies to the cerebellum and spinal cord.

This is practically a treatise on pure physiology, with little reference to the applications of this subject to practical medicine. It is a compendium of physiological facts and doctrines well suited to one who already possesses a more than elementary knowledge of the subject. A short reference to the literature is appended to each article—just sufficient to indicate where some of the chief original papers may be found. For teachers of physiology it will be found a most useful and compendious book of reference, while it fully meets the requirements of the advanced student of medicine. We can well understand that its production has been beset with many difficulties.

New Inventions.

LIGHT TOURNIQUET FOR USE DURING INTRAVENOUS MANIPULATIONS.

DURING the operations of intravenous injection of drugs and saline, transfusion of blood, and withdrawal of blood for Wassermann and Dreyer's test by vene-puncture and the like, it not infrequently happens that efforts to release the tourniquet are accompanied by disturbance of adjustment of the needle in the vein, or even by its complete dislodgment. This is not only a source of annoyance to the operator, but may lead to serious and painful consequences to the patient, especially if certain of the antisyphilitic drugs are allowed free access to the cellular tissues. Accordingly, at the request of the late Dr. A. E. Stansfeld a tourniquet was designed which could be released with the greatest ease by pressure of the finger and thumb of one hand. It has the additional advantage of being simple, inexpensive, and, if necessary, easily sterilised. The instrument (see figure) consists of a plain rubber strip, the free ends of which are held together by means of a small metal clip. The loop thus formed is placed round the arm, and by pulling on the rubber and at the same time sliding the clip towards the arm the tourniquet is tightened to the required degree. Immediately on leaving go of the clip the rubber band is firmly held, as the two lower lips at B are pulled outwards for a small fraction of an inch, thereby causing the upper lips at A to pinch the rubber, which is thus tightly gripped. There is no danger of slipping, as the greater the pull on the rubber the more firmly it is held. When it is required to release the tourniquet, gentle pressure by the finger and thumb on either side of the clip at B will cause the two lips at A to move apart. This will allow the rubber to slide freely through the clip and relieve the pressure to any required extent.



This instrument may be obtained from Messrs. Maw, Son and Sons, Aldersgate-street, London, E.C.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 28, 1920.

The Use of Figures in Medicine.

THE Council of the Royal Statistical Society is about to present to the Government an influentially signed petition urging the need of an immediate inquiry by a Royal Commission or Parliamentary Committee into existing methods of collecting and presenting public statistics. The petition draws attention to the defects and omissions of current statistics. For instance, there is no general information as to wages since the incomplete Census of 1906, nor any but the most meagre information regarding the consumption of food, clothing, and other necessaries. In fact, it is almost universally the case that persons engaged in any serious investigation have to rely on roughly approximate estimates in relation to one or more essential factors. The matters referred to in the petition are not of immediate interest to medical men; but, soundly based as our medical statistics may be, they are capable of improvement. The coördination of official statistics will be of future advantage in many directions, but the advantage will only be proportionate to the increase among medical men of the ability to employ figures.

Most of the excellencies of the Registrar-General's publications can be traced back to the genius of a single man, WILLIAM FARR, and are due to the happy accident that one who combined medical and statistical knowledge in a just proportion was allowed a free hand in days when vital statistics were not of sufficient interest to the general public for it to be worth the while of the uninformed to meddle with them. This is no longer the case; all realise vaguely that vital and medical statistics are of great importance. But, unfortunately, medical knowledge of and interest in statistics have not increased pari passu. The handful of medical men in this country who have devoted themselves to statistical science are not in a position to exert any serious influence upon the official organisation of statistics, and any development in the near future would almost inevitably be motived by the lay civil servant. The blame for this rests not with the civil servant but with the medical profession, which has been content to praise FARR and marvel at GALTON, without seriously striving to profit by the lessons of these great men. It is to be hoped that any changes made now will not be of such a character that, when a properly instructed body of medico-statistical opinion comes into existence, the system will be unamenable to remedy. Statistics can be trusted if they have been collected with care, when the larger the number of cases the greater, of course, will be the probability of the elimination of disturbing factors. The hasty accumulation of a few results is not a contribution to statistical methods, though it may afford valuable suggestions.

The Selection and Care of Airmen.

THE time is critical for civil aviation. The teams of experts picked by the war are being disbanded just at a time when organisation and research in aeronautics are most needed. Lord WEIR'S Committee, which has just reported,[1] fortunately fully recognises these facts, and suggests a central institution at the Imperial College of Science and Technology, where the professorship lately founded by Sir BASIL ZAHAROFF is to be held. In the meantime well-considered research on the medical aspects of aeronautics is not altogether in abeyance, and we welcome the appearance of two cheaply priced little manuals[2] by French doctors of experience.

Drs. MAUBLANC and RATIÉ deal with the selection of candidates for aviation, based on experience at Chartres. In addition to the ordinary clinical methods they employ certain tests which give precise results. Both systolic and diastolic pressures are measured, and the value of a relatively high diastolic pressure is duly emphasised. Healthy condition of his upper respiratory passages is of great importance to the airman, owing to the drying effect of altitude, as well as the necessity of efficient air entry. Determination of the vital capacity is recognised as being of service in the selection of the airman, the average being given as 3000 to 3500 c.cm., a lower figure than is found in this country. In the abdominal system attention is drawn to the advantage of good muscular tone and the serious drawback of any digestive ailments such as chronic dyspepsia. In examining the central nervous system no special tests are employed. Normal acuity of vision and good ocular muscle balance is demanded, although it is admitted that some successful pilots do not reach this standard. Both auditory and vestibular mechanisms are thoroughly tested. In the ultimate selection of candidates, not otherwise eliminated, great attention is paid to the psychomotor responses, which are tested by a method modified from that of CAMUS and NEPPER, a chronograph by RICHARD being employed. The average times for these reflexes are: visual 0·19, auditory 0·145, tactile 0·14 sec. Importance is attached to the constancy of the readings—regularity indicating good condition, irregularity bad condition. These reflex times are somewhat slowed by age, and largely altered by illness and accident, the responses generally becoming slow and irregular. Reflex responses are also noted to alterations of equilibrium brought about by means of a special chair, and interesting results have been obtained. It has been shown that the mean reaction times of skilled pilots to such alterations of equilibrium are quickened by training, the reduction in the time-reaction of candidate and trained pilot in one series of experiments being: sagittal variation, 0·12 to 0·09 sec.; transversal, 0·12 to

0·09 sec.; horizontal, 0·18 to 0·15 sec. Variation in these responses may serve to detect illness and fatigue, the psychomotor reactions under these conditions becoming slow and inconstant.

Another series of observations, emerging from the work of Drs. Maublanc and Ratié, concerns the effect of flying upon the blood pressure; these (for an unstated number of cases) are summarised as follows:—

	Systolic.		*Diastolic.*
Augmented in	20 per cent.	......	23 per cent.
Diminished in	30 ,,	......	7 ,,
No change in	46 ,,	......	70 ,,

Exact details as to the manner in which these experiments were carried out are not given, but the results are in marked contrast with those recorded by Professor Cruchet and Dr. Moulinier, the authors of the second manual under consideration, who have made extensive observations upon pilots, including many famous fliers, such as Legagneux and Morane. Their conclusion is that the arterial pressures in normal subjects are constantly augmented on landing. The increase in pressure is less apparent when the subject is fatigued, and may in a state of exhaustion be replaced by a hypotension. Their results have been confirmed by Ferry, and support those previously obtained by Pachon on athletes, but differ somewhat from those recorded in experiments in rarefaction chambers; the authors incline to attribute this to the effect of speed in the aeroplane. In regard to the use of oxygen, reference is made to recent experiments by Garsaux, which tend to support the view of Agazotti that the addition of carbonic acid gas, 13 parts to 100 of oxygen, improves the efficacy of oxygen for high-altitude flying. It is doubtful if such be the case when oxygen is administered continuously, before any washing out of carbon dioxide has taken place by the deepening of the respiration.

Broadly speaking, it may be said that there is no special disease of airmen. It is the strain thrown upon the various bodily systems which eventually leads to a condition of fatigue and breakdown, such as might occur in any other arduous occupation. In this respect the two French monographs confirm the results obtained by British workers. All are agreed in regard to the necessity of a special medical examination for the selection of airmen and of periodic re-examination of pilots, such as is now required by the International Aeronautical Convention. The true medical treatment of the airman is a preventive treatment, and it is important that this should be recognised, and acted upon, at the outset of the development of civil aviation. It will be a feather in the cap of preventive medicine if no new occupation disease arises, but the responsibility thrown upon medicine is here a very real one. The examining officers, forming part of a highly equipped and properly trained service, working individually or in groups, will have to be on guard against many possible sources of error.

Safety and Comfort in Child-Bed.

THE normal healthy woman would, we believe, prefer to lie in at home if she could do so with safety and a reasonable amount of comfort of body and mind. But at present in too many instances she commands neither safety nor comfort. The maternal death-rate in child-bed remains what it was more than half a century ago; in 1917 for every 1000 births 48 mothers died, and it can hardly be doubted that two or three times as many were permanently invalided. When introducing an important debate[1] last September Dr. T. W. Eden gave his opinion that the increased provision of maternity hospitals would have a beneficial effect upon this mortality, and the general consensus of the discussion confirmed this view. The Ministry of Health appears to be of the same mind in its most recent Memorandum[2] on maternity and child welfare, although observing caution in regard to the extent of the need. Two classes of patients, it is stated, clearly require provision for child-birth away from home: those who show some abnormality, and those whose domestic conditions are unfavourable. The first class is of known or ascertainable extent, and the provision should be in the nature of beds in maternity hospitals, of which several forms are described and illustrated in the Memorandum. The second class arises largely from an emergency which time and appropriate handling may relieve. Comfort in child-bed has been sadly diminished by the house famine and the disastrous lack of domestic service. A typical example drawn from the daily press of Tuesday is that of an ex-naval man living with his wife and two children in a single room and applying for accommodation in the workhouse after a year's fruitless search for other quarters. Under such conditions child-bearing at home is unthinkable, and in our own large towns, as in Paris,[3] some temporary provision is very urgent. The report of a conference convened in November by the Central Nursing Council,[4] and now issued, throws additional light on the difficulties of maternity nursing as they exist in London at the present time. It is there stated, without contradiction, that the bulk of confinements in London are now attended by midwives, who are often too overwhelmed with work to nurse their own cases, while trained nurses seem loath to work under them. Sir William Collins, in summing up the lessons of this conference, dwells on the need for municipal maternity hospitals, but he puts, as the first and foremost want, a more ample supply of home helps. Home-helping may well provide an outlet for those who possess a talent for domestic service.

Rural Water-supplies.

AN instance of some of the difficulties besetting the provision of a rural water-supply is afforded by a recent number of the *Municipal Engineering and Sanitary Record*, in which is given an account of the present deadlock in the arrangements for providing a particular rural parish with a wholesome supply of water. It appears that the present supply, which is derived from a number of surface wells subject to pollution, has been condemned by the medical officer of health. The rural district council is prepared to take steps to provide a satisfactory public supply, but the project is opposed by the principal ratepayers of the parish, who carried the day at a parish meeting summoned to consider the question. It seems likely that the resolution there passed, however unanimous, may not adequately express the opinion of the poorer inhabitants largely concerned, who may be unwilling to take sides against their more important neighbours. The poorer inhabitants are, therefore, to be compelled to continue in the use of their polluted water-supplies owing to the lack of public spirit of the richer members of the community, who can probably manage either to safeguard their personal supplies of water or to replace them by some pleasant substitute. This is far from being an isolated example of the many problems which confront those responsible for the provision of water-supplies in rural districts; these problems are largely the product of inertia and of selfishness in combination. In such a case as the above, the rural district council ought to overrule the opinion of the parish, and should apply its powers under Section 51 of the Public Health Act, 1875, to provide a public water-supply. But the councils of rural districts are cautious and conservative to the last degree, and they know that the Act in question, while conferring the power, does not impose the duty of providing such a supply. There is more than one weak link in the legal machinery in this respect. For example, Section 3 of the Public Health (Water) Act, 1878, refers to the "*duty* imposed on them [rural authorities] by the Public Health Act, 1875, of providing their district or any contributory place ...... with a supply of water, where danger arises to the health of the inhabitants from the insufficiency or unwholesomeness of the existing supply," &c.; yet the most diligent search fails to trace in the 1875 Act the statement of any such obligation as distinct from the grant of such powers. To the non-legal mind, intent upon public good, it appears that the law on the subject needs overhauling, with special reference to the substitution of obligatory for permissive clauses.

The officers of rural authorities may find useful leverage to hand in the new housing schemes. Under Section 6 of the Public Health (Water) Act, 1878, every house erected after March 25th, 1879, must have a sufficient and wholesome supply of water for consumption and for domestic purposes, and the house cannot be occupied until a certificate to that effect is given by the sanitary authority on the report of its inspector of nuisances or medical officer of health. In the past houses have crept into existence where that certificate has been obtained, almost as by stealth, in cases where the water-supply was not really above suspicion, and where the only excuse was that the house, like the baby in the old story, was "only a little one." But a new attitude is needed with the more serious question of the erection of houses in number previously never dreamt of. The officers in question may now not feel justified in approving water-supplies in bulk where before they approved, with some qualms at times, supplies to individual houses erected at infrequent intervals. If their reports do in effect prove adverse, the district council will be faced with two alternatives—to drop the housing scheme, which will be likely to lead to trouble with the Ministry of Health, or to screw up its courage to the provision of a proper water-supply. It is to be hoped that the latter alternative will commend itself even before the pressure of public opinion and of the Ministry compels its adoption.

Annotations.

"Ne quid nimis."

IN MEMORY OF WILLIAM OSLER.

A PUBLIC meeting has been called in the lecture theatre of the Museum at Oxford on Saturday, March 6th, at 3.30 P.M., to consider what steps should be taken to perpetuate, in some appropriate manner, the memory of Sir William Osler. Invitations have been sent out in the names of Arthur Thomson (Dr. Lee's Professor of Anatomy), Georges Dreyer (Professor of Pathology), C. S. Sherrington (Waynflete Professor of Physiology), J. A. Gunn (Professor of Pharmacology), P. E. H. Adams (Reader in Ophthalmology), E. W. Ainley Walker (Lecturer in Pathology), A. P. Dodds-Parker (Lecturer in Applied Anatomy), A. G. Gibson (Lecturer in Morbid Anatomy), Wm. Collier (Litchfield Lecturer in Medicine), and H. C. Bazett (Welsh Lecturer in Clinical Physiology), all immediately concerned with the teaching of medicine in Oxford. Many University officials and heads of houses have intimated their intention of being present. Notifications of the intention to be present should be sent to the interim-secretary, Professor Gunn, at the Museum, Oxford.

THE WAR EMERGENCY FUND OF THE ROYAL MEDICAL BENEVOLENT FUND.

THE National Relief Fund has made a substantial grant of £10,000 to the War Emergency Fund to be used for general purposes. This enables the War Emergency Fund to enlarge the scope of its activities in a practical manner. The Committee of the Fund will now be able, for example, to make liberal grants for the education of children of medical men who held commissions in the medical services during the war, and we cannot conceive any better destination for the money at their disposal. Next, perhaps, to the education of his children the principal anxiety of the medical man is that death in harness should not imply immediate poverty for his family, and this apprehension, also, takes its rise largely from the feeling that such poverty must lead to lack of education. But the medical men who have taken thought for the position by insuring their lives, have found in existing circumstances the payment of premiums a heavy burden, and the relief of this responsibility is one direction which grants from the War Emergency Fund may very usefully take. There is also the burden of the loan to purchase house or practice; interest charges are pressing heavily on many of the doctors who were away with the colours, while timely help will enable them to make good a position which has been jeopardised by world events, and not by personal rashness. We are able to say that any officers applying for assistance on such grounds as we have set out will be heard sympathetically. Communications should be made to the Honorary Secretary of the Fund at 11, Chandos-street, Cavendish-square, London, W. 1.

THE BLOOD PRESSURE IN PULMONARY TUBERCULOSIS.

It is a curious fact that in spite of numerous investigations into the blood pressure in pulmonary tuberculosis, and the unanimity of most observers, the diagnostic and prognostic significance of a low blood pressure in doubtful cases of tuberculosis is commonly overlooked. French and American writers attach great importance to this sign, and both Papillon and Regnault have found it a useful guide at a stage when the physical examination of the chest is negative. German writers are, on the whole, less impressed by the diagnostic value of this sign. In a recent publication,[1] Reinhold Nauclèr has combined a review of the literature of this subject with a long series of original investigations. These showed that though considerable individual variations of the blood pressure might be found in groups of cases classified according to Turban, yet the average pressure sank uniformly with the extent and severity of the disease. And even in the matter of individual cases the highest pressures were observed in Turban's stage I., the lowest in moribund cases. Both diastolic and systolic pressures were lowered by the disease, but the diastolic was less affected than the systolic pressure. It was also noted that the fall of the pressure depended rather on the malignity of the disease than on its anatomical distribution; in some cases characterised by considerable malaise, but by few and insignificant chest signs, the pressure was extraordinarily low. Measurements of the blood pressure in the same individual over a long period sometimes showed that a comparatively high pressure might come down with a run if the disease was rapidly progressive, whereas in other cases an originally low pressure might fall only a trifle during the further course of the disease. A comparison of the blood pressure with the weight curve showed that the average pressure was higher among those who gained weight than those whose weight was stationary; and in these again it was higher than in those who lost weight. There was also a definite parallelism with regard to the blood pressure and hæmoptysis. Not only was hæmoptysis comparatively frequent among the subjects of a high blood pressure, but the severity of the hæmoptysis also corresponded with the height of the blood pressure. Nauclèr contrasts these findings with those of Professor Bang and others, who have argued that the pressures in the systemic and the pulmonary circulations are independent of each other. It may be, as Nauclèr suggests, that the coincidence of a high systemic blood pressure and hæmoptysis is not direct, and that both may be due to a third common factor. As to the value of the blood pressure in the early diagnosis of tuberculosis, it is disappointing to find that though it was subnormal in 60 per cent. of Nauclèr's patients in the first stage, both in this and in the second stage perfectly normal pressures occurred frequently. It would therefore seem that a low pressure is very suggestive of tuberculosis in doubtful cases, but a normal pressure must not be interpreted as excluding tuberculosis.

THE CHADWICK PRIZEMEN.

The Chadwick trustees have awarded a gold medal and a prize of £100 to each of the two medical officers in the British service deemed to have distinguished themselves most in promoting the health of the men under their care. The selection has been made by the director-generals of the medical services, and at 5 P.M. on Monday, March 8th, in the lecture-room of the Royal Society of Arts, Sir Robert Hill will present Surgeon-Commander Edward L. Atkinson, D.S.O., R.N., and Sir John Goodwin will present Brigadier-General W. W. O. Beveridge, D.S.O., A.M.S., to Sir William Collins, who will make the presentation.. At the conclusion of the ceremony Sir John Goodwin will deliver the first of a series of three lectures on Military Hygiene in Peace and War.

PSYCHICAL SCIENCES.

In two numbers of the *Anglo-French Review*—namely, those for December, 1919, and January, 1920—there appears an interesting article by M. Camille Flammarion entitled, Les Sciences Psychiques. The celebrated French astronomer expresses his belief that the answers to questions, manifestations of levitation, and other phenomena obtained by or through the agency of mediums are genuine manifestations of the existence of a force existing in the universe for which at present there is no name. He quotes what he wrote in 1906: "Psychical manifestations confirm that which we know from other sources—namely, that the purely mechanical explanation of Nature is insufficient and that there exists in the Universe something besides apprehended matter. It is not matter which rules the world; it is an element which is both dynamic and psychic." In another article written in 1888 he said, "The Universe is an intelligent, unknowable resultant of forces (dynamisme)." From observations which he has made at varying intervals from 1861 and onwards he concludes: (1) That gravitation can be counterbalanced by contrary forces; (2) that the human being is possessed of an invisible force which can move objects more or less heavy without being in contact with them; (3) that the levitation of heavy objects—for example, tables—can be brought about by the simple contact of the hands of experimenters whose wills are united in the desire to obtain such levitation; (4) still more, such movements can be obtained without any contact—for instance, a chair will move towards the experimenter at his wish; (5) answers may be obtained to questions, such answers being given by knocks corresponding to a conventional code of letters of the alphabet. He does not pretend to explain this force, he merely affirms its existence whether it be in ourselves or outside. As regards communications by knocks, he gives an instance which happened when he was present at a seance, when a long message was received of which we have only space to quote one sentence, "Liesnoc nob nu zevius." If the order of the letters is reversed this reads "Suivez un bon conseil." Another began as follows without any stops:—

---

[1] Acta Medica Scandinavica, vol. lii., Fasc. III., 1919.

"Acmairsvnoouussevtoeussbaoinmsoentsfbiideenlteosuss."

Take every other letter and this reads, "Amis, nous vous aimons bien tous, car vous êtes bons et fidèles." M. Flammarion says that he can hardly suppose that this communication was given by trickery on the part of the medium, for how difficult it would be to do. It certainly would be, but after reading "The Road to En-dor"[1] we think that the ingenious Mr. Jones could have produced the same or a similar sentence. The communication which was delivered, beginning at the end, is especially interesting, as it may have been communications of this kind which gave rise to the indictment of the seventeenth-century witch-finders that witches said their prayers backwards. We can agree with M. Flammarion when he says that there is an unknown force in or at the back of the universe "with which our five senses only put us in very imperfect relation." If we read M. Flammarion rightly, it would seem to be the same as the stoic "anima mundi" or "mens divina," referred to by Virgil in the fourth Georgic and the sixth Aeneid. This force can communicate with us in divers fashions, amongst others by mediums, but in brain transmission this becomes difficult, as M. Flammarion allows, and is often completely altered (dénaturée). But as for the levitation of heavy bodies we think that the matter is still not proven.

RELAPSING PHLYCTENULAR KERATITIS IN CHILDREN.

RELAPSING phlyctenular keratitis in children is one of the most unsatisfactory conditions which the ophthalmic surgeon is called upon to treat, especially in hospital practice. That there is some connexion between these obstinate cases and tuberculous infection is highly probable, but exactly what this connexion is has never yet been clearly proved. The theory put forward by Mr. C. K. Wolff, of Amsterdam, in a paper on the Character and Treatment of Scrofulous Inflammations of the Eye in the February number of the *British Journal of Ophthalmology* is somewhat novel. He suggests that a patient subject to phlyctenular disease has formerly had in his eye a tuberculous process which, though cured by the natural power of resistance to the organism, has left the eye hypersensitive to the tuberculous poison. According to him the patients can almost always be shown to have tuberculous glands of the neck on the same side as the affected eye, and to complete his theory we only have to accept the hypothesis that tuberculous poisons are now and then mobilised out of the tuberculously inflamed lymph glands. Acting on this assumption, Wolff has attacked the infected cervical glands by extirpation with, on the whole, favourable results. However, since renewed inflammation of the glands occurred rather often he now prefers to treat them by X rays, and the effect of this treatment on the recurrences of phlyctenular disease has been decidedly favourable. The number of exposures employed in any particular case varied from two to ten. This method of treatment has only been tried by him since 1916, but it seems sufficiently promising to warrant the hope that we may hear more of it in the future.

A WELFARE MEDICAL SOCIETY.

THE work of successfully conducting an infant welfare centre is one of genuine difficulty. It not only demands a close acquaintance with many types of mother and many types of child, but there is also need of detailed knowledge of subjects which find no place in the present curriculum of medical schools. The literature of these subjects is perplexing, inasmuch as there appears to be no agreement even on points of fundamental importance, and there is little authoritative teaching. In view of all this a Society of Medical Officers of Maternity and Child Welfare Centres has been formed and will hold its first meeting on Friday, March 26th, at 5 P.M., at Bedford College, Regent's Park. A large number of medical officers in charge of centres have already joined the society in response to an invitation which was issued by circular. At the first meeting a draft constitution will be presented and a tentative programme for meetings in London and in various centres in the country. It is hoped that any medical officers in charge of centres who have not received an invitation to join the society will communicate with the secretary, Miss J. Halford, National League for Health, Maternity, and Child Welfare, 4, Tavistock-square, London, W.C. 1. It is of great importance that the work now being inaugurated at scores of new centres should not become stereotyped and commonplace, and we believe that this can be most surely prevented by the interchange of thought for which this new society offers facilities.

PROBABILITY-DIAGNOSIS IN MALARIA.

THE first paragraph of Colonel M. D. O'Connell's letter on the Diagnosis of Malaria, which appears in this issue of THE LANCET, would, we think, carry conviction to most minds of the value of microscopical diagnosis in malaria in the case of armies in the field, although Colonel O'Connell himself seems to remain unconvinced. He states a case against this method, basing it on two grounds: (1) that parasites may be present in the blood of individuals who display none of the ordinary symptoms of acute malaria; (2) that active malaria may be present notwithstanding failure to find parasites in the blood. In illustration of his first point he quotes the well-known fact that in countries where malaria is endemic the blood of native children, apparently in good health, may swarm with parasites. But this occurs in the case of natives only, and has no bearing on the significance of a heavy blood infection in adults who are residing as foreigners in the district. In the latter case the blood infection always forms a part of the picture of an acute malarial attack. As regards Colonel O'Connell's second point, it is true that in certain forms of malaria there may be periods in which no parasites are demonstrable in the peripheral blood, but this is no argument against blood examination; on the contrary, it is an argument in favour of repeated blood examination. If this is done proof will be forthcoming sooner or later of the true nature of these elusive forms of malaria, a proof which is often unattainable by any means other than microscopic examination of the blood. It is surely rather wilful to quote Sir Patrick Manson's experiment of 1900 as evidence against the routine use of the microscope in the diagnosis of malaria, whether under the conditions of active service or otherwise.

---

[1] Reviewed in THE LANCET, Feb. 14th, 1920 (p. 389).

We print in this issue a case of toxic anæmia, recorded by Dr. J. G. Forbes and Dr. R. F. Lunn, and assumed by them to be post-malarial, although they failed to demonstrate the plasmodium in the patient's blood. The record of such a case might be held to bear out Colonel O'Connell's poor opinion of the value of blood examination. But in point of fact no one maintains that a positive blood film is invariable in all cases of acute malaria; if it were so, medicine would lose much of its interest for the inquiring mind. The film may be taken at the wrong time in relation to the pyrexia, or the patient may be under the influence of quinine; or (rarely) the activities of the parasite may so seldom extend to the peripheral blood that the chances of finding it there are very small. No single clinical or pathological test is infallible; but it would show a lack of perspective to focus the attention on a small group of exceptional cases, and on these to found an indictment against a test which was of proved value in the war areas where malaria was prevalent. In the case recorded there were only two negative blood examinations before quinine was given, the effect of which was promptly to reduce the temperature. Examination during the apyrexial period was likely to yield a negative result. The demonstration of parasites in the blood is, in fact, only one element in the diagnosis of malaria. Mathematicians would tell us that the result of examining the blood in malaria does no more than establish a probability-diagnosis. But in the ordinary affairs of life probabilities when they reach 90 per cent. are considered worth a wager, and the clinician is right in placing a high value on blood examination in malaria.

A CASE OF PLAGUE IN THE PORT OF LONDON.

THE Ministry of Health has been notified of the occurrence of a case of plague on the s.s. *Alps Maru.* The ship arrived in the Port of London from Japan and entered the Millwall Dock a fortnight ago. One of the crew fell sick the next day, and as he was suspected to be suffering from plague he was removed to the isolation hospital. The diagnosis of plague has now been confirmed by the bacteriologist of the Ministry from material obtained from the patient. The vessel has been removed to the Port mooring station for infected ships, and all necessary precautions have been taken by the Port Sanitary Authority to prevent the spread of infection.

THE BREAD POSITION IN FRANCE AND GERMANY.

THIS country may well be appreciative of the policy of the Food Controller and his scientific advisers, which resulted in the fact that during the war bread never once came under a definite rationing order. The nation was asked voluntarily to reduce its bread-eating, to supplement the diminished amount of carbohydrates thus entailed with other cereals or potato, and to give up highly milled flour. The nation replied right loyally to that paragraph of the King's proclamation issued on May 2nd, 1917, which ran: "And we do for this purpose more particularly exhort and charge all heads of households to reduce the consumption of bread in their respective families by at least one-fourth of the quantity consumed in ordinary times; to abstain from the use of flour in pastry; and, moreover, carefully to restrict, or, wherever possible, to abandon, the use thereof in all other articles than bread." Things happened differently in France and in Germany, and the bread position in these countries is still difficult, as is shown by the following excerpts taken from the *Economic Review* (Feb. 18th, 1920):—

FRANCE.

Bread and Grain Regulations.

France is to have no bread-cards, but bread is to be dearer. The following Order has been issued:—

Home-grown wheat will be bought from the growers at Fr. 73 per quint., but sold to the millers at Fr. 76, the price of imported wheat. The maximum price of flour will be Fr. 93 per 100 kg. The prefects will fix the price of bread in their Departments, having regard to the costs of flour, transport, and bread-making. A bread-ticket, giving the right to 400 grm. of bread a day at the present price, will be available for: (*a*) heads of families with at least 3 children, for each child under 16; (*b*) widows with at least 2 children, for each child under 16; (*c*) war pensioners with an invalidity of at least 50 per cent.; (*d*) the aged, infirm, and incurable drawing benefits under the law of 1905.

As from Feb. 20th wheat flour, pure or mixed, may not be used in the manufacture of fresh pastry. Millers may not sell wheat flour or flour made of the secondary bread cereals for other purposes than bread-making. People are reminded of the penalties for feeding animals on wheat, flour, or bread. (*Œuvre*, Feb. 4th.)

GERMANY.

Reduction of the Bread Ration.

A semi-official message to the *Berliner Lokal-Anzeiger* states that the delivery premiums have not improved the grain-supply as much as was hoped, and in consequence the flour ration must temporarily be reduced from 260 grm. to 200 grm. per day. (*Köln. Ztg.*, Feb. 3rd.m.)

This will entail a reduction in the bread ration from 2350 to 1900 grm. per week. (*Schles. Ztg.*, Feb. 3.m.)

Grave Situation in Munich.

According to a confidential statement, which has found its way into the Munich press, the supply of bread, corn, and flour in Munich will suffice only to Feb. 16th, and even before that date the bread-supply will give out. The town holds only 15,000 ctr. potatoes and 10,000 eggs. Butter and margarine are completely lacking. There is enough meat to supply 200 grm. weekly for four weeks. (*Köln. Ztg.*, Feb. 4.ii.)

The future of the general health of nations which had a markedly inferior supply of food during the war is still uncertain, but the effects of such restrictions, in which a limited allowance of good bread counts, will probably be active for many years.

THE VACCINE-ANTITOXIN TREATMENT OF DIPHTHERIA.

Dr. F. M. Wood has described[1] a vaccine-antitoxin treatment of diphtheria, which he has used with success, and which has been adopted by the Chicago Department of Health. In April, 1913, prior to the announcement of Behring's toxin-antitoxin method, this treatment was first used. A vaccine was made from a case of diphtheria, and a pure culture obtained. A vaccine of 300 to 500 million bacilli and 1000 units of antitoxin were simultaneously, but separately, injected into three children having diphtheritic membranes in their throats. By the third day the membranes had disappeared. Two more doses of vaccine of 500 million bacilli were administered at intervals of three days. On the tenth day cultures were taken and found negative. Dr. Wood has used the method repeatedly in the last six years with uniform success, but he advises caution. If the vaccine can be given before the disease has progressed more than four days, and an excessive amount of toxin has not formed, the initial dose may be 300 million bacilli. But if the disease has progressed more than four days, if membrane formation is excessive, and if tonsils, nares, and pharynx are involved, there is great toxæmia. It is then best to administer 100 million bacilli and 3000 to 5000 units of antitoxin, according to the severity of the toxæmia. Thus the dangers of pneumogastric paralysis may be avoided. The dose of vaccine may be increased to 300 million bacilli at the next dose and later to 500 million, as improvement suggests. The antitoxin may be repeated as required. Thus both the destruction of the bacilli and the neutralisation of the toxin are achieved. Dr. Wood claims the following advantages for this method: The production of toxin is stopped, the patient producing his own antitoxin from the time the vaccine is administered. The dose of antitoxin renders inert the toxins already formed and thus prevents paralyses and heart failure. By using the method in carriers the bacilli are destroyed and epidemics are stopped. It may also be used to immunise contacts. In cases of diphtheria the throat is freed from bacilli in 10 days, thus shortening the quarantine period and enabling children to return to school without danger to the others. Dr. Wood thinks that the ultimate result of this treatment would be the efficient control of diphtheria epidemics as small-pox epidemics are controlled by vaccination.

---

[1] New York Medical Journal, Jan. 10th.

THE CEREBRO-SPINAL FLUID IN MULTIPLE SCLEROSIS.

Dr. J. E. Moore,[1] of Baltimore, describes the results of the examination of the cerebro-spinal fluid in 28 cases of multiple sclerosis under treatment at the Johns Hopkins Hospital. In 20 of the cases the clinical diagnosis was certain; in the remaining 8 it was doubtful. In the first group the Wassermann reaction was negative in all cases, both in the blood and cerebro-spinal fluid; in 8 cases there was a pleocytosis of more than 5 cells; and in 18 cases Lange's colloidal gold test was positive. In the second group the findings were the same, except for the gold test, which was positive in 3 cases and negative in 5. These figures show that the spinal fluid picture is fairly constant, and that, other things being equal, such findings are a strong argument in favour of a diagnosis of multiple sclerosis.

DEATH OF DR. JAMES EMERSON REYNOLDS.

CHEMISTS will remember Dr. J. Emerson Reynolds, who died suddenly at his residence in Kensington on Feb. 19th in his seventy-seventh year, most by his admirable series of researches on silicon compounds, his synthesis of thio-urea, and his conviction that the elements have come into existence one after the other in the order of the atomic weights, starting with the smallest. He regarded each atomic mass as representing a stable aggregation of the fundamental stuff, a primal "Urstoff"—the protyle of Crookes. Modern developments in scientific work are rapidly accumulating evidence in favour of Reynolds's views. Students of Dublin in the seventies, eighties, and nineties will learn with regret of the death of their old teacher, who taught chemistry in Dublin from 1873 to 1903. For the first two years of that time he was professor of chemistry in the school of the Royal College of Surgeons, and for the subsequent 28 in Dublin University. His image stands clear in many a medical man's memory as one of the most notable at the beginning of his student career. He was a clear and comprehensive lecturer, illustrating his words with well-chosen and perfectly arranged experiments which never failed to "come off." His researches gained for him the Fellowship of the Royal Society in 1880. In 1901 he was elected President of the Chemical Society. He qualified early in his career to practise medicine, but his bent was chemistry. He resigned the chair of chemistry at Dublin in 1903, and then left his native country for London.

THE RANGE OF GENERAL PRACTITIONER SERVICE.

AN important case has just been heard by the referees appointed by the Scottish Board of Health to adjudicate a dispute between the Glasgow Insurance Committee and the Local Medical Committee. The question for decision was—

> Whether the operation of suturing tendons of fingers is a service of a kind, which can, consistently with the best interests of the patient, be properly undertaken by a general practitioner of ordinary professional competence and skill.

The referees were Mr. John Wilson, K.C., Dr. A. J. Campbell, and Mr. Frederick K. Smith, surgeon to the Royal Infirmary, Aberdeen. The Insurance Committee contended that the operation of suturing tendons of fingers was not one requiring special skill, but the referees held that the evidence of the distinguished surgeons called by the Medical Committee established a distinction between operations affecting tendons on the back of the hand and tendons on the front. The special risks and difficulties of suturing tendons in the palm was pointed out, and amongst others that—

> The sheath which encloses the palmar tendons may be the means of carrying septic material proximally into the palm or into the forearm, and, moreover, the proximal end of the severed tendon being subject to retraction into the sheath may involve an operative enlargement of the original wound. Further, the conditions existing in the patient's dwelling or in another dwelling house under which the general practitioner would generally have to operate, would increase the risk of sepsis, especially when the fingers have been seriously crushed.

Witnesses for the Medical Committee were clear that in Glasgow it was the general rule to have operations such as that in question performed in one of the hospitals. On the evidence before them the referees, without pronouncing on the skill required in the particular case, decided that no general or absolute rule could be laid down to the effect that suturing of tendons of a finger was a service of a kind which could, consistently with the best interest of the patient, be properly undertaken by a general practitioner of ordinary professional competence and skill.

Professor F. de Lapersonne, assisted by Professor Terrien and Drs. Velter, Prelat and Mombrun, will conduct a revision course in the ophthalmological clinic at the Hôtel-Dieu, commencing on May 11th and continuing every day entil the end of June. The fee is Fr. 100 and the number of places limited to 40. Application should be made to the Secretariat of the Faculty of Medicine, Paris.

---

MEDICINE AT TRISTAN DA CUNHA.

By H. St. C. Colson, M.B., B.S. Lond.,
SURGEON LIEUTENANT-COMMANDER, R.N.

I HAD the opportunity last autumn of landing at Tristan da Cunha, a small island in the South Atlantic, 1200 miles from the nearest land. There are no doctors, lawyers, clergymen, police, or money on this island, and I believe the last medical report was written in 1902. My stay on the island only lasted a few hours, but I am enclosing a short report, thinking it will be of interest to readers of THE LANCET.

General Features.

Tristan da Cunha, a British possession, is an island mountain of volcanic origin in the South Atlantic Ocean, latitude 37–5–50 S., longitude 12–16–40 W. It is circular in form, with a circumference of about 21 miles, diameter about 7 miles, height 7640 feet. Volcano extinct during historic times. The island was discovered by the Portuguese navigator Tristão da Cunha in 1506, and was occupied by the British in 1816. The nearest inhabited land is the island of St. Helena, 1200 miles to the north. The inhabitants of the island number 111, and consist of 22 families living in 18 houses. Although the majority of the people are quite white, some of them are slightly coloured. This colour is fast dying out and originated from five women who were imported into the island from St. Helena in 1826 and the wife of Corporal William Glass, who was a Cape coloured woman.

The people appear to be clean and healthy. The clothing of the women is simple, consisting of a blouse and skirt and a handkerchief tied over the head. That of the men is varied, probably due to the fact that most of their clothes are obtained from passing ships. Their shoes are made of bullock hide and are very primitive and only last a few weeks. The islanders are abstemious, no alcohol being consumed on the island, and some of the men do not smoke. This seems to be a case of necessity rather than choice, as men visiting the ship were willing to take refreshment in the form of spirits or wines. Their speech is slow and very broad, and they have only a limited vocabulary. Some of their words are abbreviated by a syllable being left out, but this is probably due to ignorance in pronunciation.

Their houses are scattered over the settlement, and are built of thick stone walls and roofed with tussock grass. They consist of one large room, divided by wooden partitions into a sitting-room, a bedroom, and a kitchen. In the majority of houses the sitting-room has a large open fireplace. Most of the houses are provided with glass windows which do not appear to open. The doors are divided into a lower and upper part, presumably for light and ventilation. Penguin oil is used for lighting the house after dark, giving a small, bad light. The sanitary arrangements are primitive, a bucket of sand being used and the contents are carried away and thrown into the sea. The water-supply is derived from a stream which has been diverted slightly from its natural course to run through the settlement. Water needed for drinking and washing purposes is taken from this stream as required.

The produce of the island consists of beef, mutton, pigs, fowls, geese, eggs (poultry and sea-birds'), butter, and potatoes. The potatoes are made into a coarse kind of flour, but this is only used when other flour is unobtainable. Fish are caught by the inhabitants to supplement and vary their food. Other necessaries, such as flour, sugar, and salt, are obtained from passing ships by barter.

There are meteorological instruments on the island, but no records have been kept since the visit of Rev. — Barrow, who kept them from Feb. 15th, 1905, to March 31st, 1909.

Extract from Mrs. Barrow's book—

Max. temp., Feb. 15th. 1905–August 16th, 1908, 77·8 F.
Min. ,, ,, ,, ,, ,, 37·9° F.

The rainfall in 1908 was 64·84 inches.

General Health of the Inhabitants.

This seemed to be good. The oldest inhabitant was Betty Cotton, aged 89 years, and except for some slight failure of vision was perfectly well. There have been six deaths reported in the last eight years—

Andrew Repetto. 9.2.11. Aged 44. Disease of chest.
Lucy Green. 1.8.12. Aged 63. Insanity.
Albert (? Alfred) Green. 1.10.15. Aged 30. Insanity.
Eliza Hagan. 11.10.15. Aged 75. Old age.
Joseph Fuller Glass. 25.8.15. Aged 47. Fever.
Elizabeth Glass. 25.8.16. Aged 33. Disease of womb.

No further information respecting the cause of death could be obtained. Epidemics are practically unknown, but after the visit of a ship the islanders suffer from "colds." The recent influenza epidemic was not experienced in the island. There appears to be no venereal disease among the islanders. Three women were pregnant, and expected to be delivered shortly. They are usually assisted by one or more of the married women. Minor complaints were those of chronic rheumatism, of which two cases only were seen in old people, failure of eyesight, asthma, lumbago, and hernia.

Interesting Cases.

The following cases were of most interest:—

Benjamin Louis Swain, aged 50.—This man had both upper extremities deformed from birth. His mother, Mrs. Susan Swain, is 70 years of age, and active and well. His four brothers and four sisters are normal. Deformity: Right arm. There is a small humerus articulating normally at the shoulder-joint, and much enlarged at the lower end (? fused carpus). There are two metacarpals articulating with the lower end of the humerus with two fingers, each having two phalanges. The left arm consists of a humerus smaller than that of the right side, which does not appear to articulate at the shoulder-joint. The lower end of the humerus appears to be prolonged into an ulna, but no joint is present. There are three metacarpals attached to the lower end of this, with thumb and two fingers attached. Both his arms and fingers can be used to a limited extent for picking up objects, &c. He also suffers from attacks of syncope, which can be accounted for by a degree of aortic regurgitation which is present.

Christopher Green, aged 14. His mother stated that he had not been able to speak since he was born. The boy, described by the islanders as simple, seemed an idiot. He was very shy and laughed foolishly on being spoken to, and he was only able to articulate very rudimentary sounds. There was some fibrosis of the centre of his tongue, but this did not seem sufficient to account for his lack of speech. His mother, prior to his birth, had been lost on the mountain for 24 hours, and had subsequently suffered from pains in the head and attacks of syncope. Except for his mental condition the boy seemed well grown and physically fit.

William Rogers, aged 28. This man complained of being unable to see at twilight at all, although his sight was normal in the day and by artificial light. There was no time to examine his eyes.

Mary Glass, aged 81. This woman suffered from chronic rheumatism in her right foot. She also had congenital deformity of the thumb of her right hand, the terminal phalanx being replaced by two small thumbs of two phalanges each.

Florence Swain, age 16. This girl fell down the mountain nine years previously and fractured both legs, which were "set" by the late Andrea Repetto, one of the inhabitants. He also amputated two toes of her left foot which were badly crushed. She had scars of fractures in both legs and her left foot is much deformed and scarred, causing difficulty in walking.

It will be noticed that two cases of insanity are shown among the deaths for the past seven years, and also that one boy, Christopher Green, is an idiot. These might suggest that there is an in-breeding in the island, but there is nothing to show that this is the case. The colony started in 1816 when a garrison was sent by the Cape Government to occupy the island. In 1817, when the garrison was withdrawn, three men asked to remain, and the chief of these was Corporal William Glass, who had with him his Cape coloured wife. Later, three men were shipwrecked on the island and five men, being bachelors, asked the captain of a whaler to bring them wives from St. Helena. This was done and a widow (with four children) and four other women were imported. Twenty years later Peter Green, a Danish sailor, was shipwrecked on the island, and in the next decade Rogers and Hagan came from America and, in the early "nineties," Repetto and Lavarello—two Italian sailors—were shipwrecked there. The second, third, and fourth generations are still living in the island and there is no evidence of intermarriage.

Mrs. Lucy Green, who was reported to have died at the age of 75 from insanity, was the daughter of Peter Green (the Danish sailor) and one of the four daughters of the coloured widow who came from St. Helena. The registered cause of death was probably inaccurate. There was no doctor present, and a delirious condition might easily be taken by the islanders for insanity. The case of Albert Green, also reported to have died from insanity, is probably similar to the above. Christopher Green was the grandson of Peter William Green, one of the original settlers, and no intermarriage could possibly have taken place in this family. The two cases of congenital deformity reported above showed no signs of intermarriage in their families.

Medicine was given to those islanders who were in need of it. No supplies of medicine were left on the island. A ship of the Houston Line left medicines for the use of the inhabitants in 1916, but they were thrown by the islanders into the sea, as they did not know how they should be used and feared to be poisoned.

I vaccinated 38 children at the request of their parents, of whom the eldest was 15 years of age.

H.M.S. *Yarmouth.*

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Extinction of the Typhus Epidemic in Paris.

THIS little epidemic was confined to the seminary of Saint-Sulpice, which serves to lodge refugees, among whom there happened to be Polish workmen infected with the disease. They are now convalescent, but the incident has demonstrated a defect in the organisation of hygiene in Paris. Special personnel was insufficient for the disinfection of the rooms, and this could only be carried out with the help of soldiers. The civilian services possess no single transportable stove. Beside this, in consequence of the house shortage, no place could be found to isolate the other inhabitants of the seminary. Dr. Roux, director of the Pasteur Institute, has renewed a suggestion made by him long ago to create a kind of lazaret on an open space near Paris with cement floors, on which hutments could rapidly be erected in case of need from material stored in adjacent hangars. In this way an emergency might be tided over in case of epidemic or flood.

The Rising Birth-rate.

The campaign goes on for increasing the accommodation for lying-in women. The fifth commission of the municipal council has voted an immediate credit of 100,000 francs in order to subsidise the midwives of benevolent institutions at a figure of 50 to 70 francs for each case of labour conducted at home, and to allot to each parturient woman an assistance of 50 francs. It is further proposed to cover an average fee of 20 francs for each visit paid at the home by the doctor of the Assistance Publique. M. Mesurier, director of the Assistance, stated that he had been able to find 300 additional beds for parturient women: 90 at the Hôtel-Dieu, 40 at St. Antoine, 50 at the Lariboisière, 100 at St. Louis, and 20 at the Edith Cavell Hospital.

The Schick Reaction.

M. Jules Renault has communicated to the Academy the result of his observations on 381 cases in which he has used the Schick reaction with diphtheria toxin. The details of the method were given in your issue of Jan. 24th (p. 192). If the reaction is positive the subject is regarded as receptive for diphtheria, if negative he is refractory or immunised in advance. The reaction may therefore be of great importance, during the course of an epidemic of diphtheria, in determining the subjects likely to contract the disease, when preventive serum can be given. Of course the reaction does not do away with the necessity of searching out diphtheria carriers who may be found as much among refractory as receptive subjects.

Chemo-therapy of Morphinism.

MM. Brissemoret and Challamel suggest a new method of "demorphinisation" which should be of value if confirmed. In morphinomaniacs a daily dose of 10 to 20 cg. of berberine combined with helenin, a stearoptene extracted from elecampane, is given. The authors claim to create thus a euphoria equal to that of morphine itself, while the two substances named are regarded as completely inoffensive.

The School of Social Effort "pro Gallia."

A school for social effort has just been inaugurated at Paris in the Musée Social, 5 Rue las Cazes, under the presidency of M. Jules Siegfried, deputy for le Havre. This school is designed to play an important rôle in the new and more methodical organisation of society. It plans to give social education and instruction to those who, more familial than professional by training, have decided to adapt themselves to the needs of the moment. The special aim is to provide a qualified personnel for social services, of which the number increases every day, such as children's nursing, school nursing, district nursing, and health visiting. Those who propose to be secretaries of welfare centres, directors of physical education, heads of orphanages, holiday homes, child-gardens, and so forth, will also receive training.

The late Dr. Triboulet.

Dr. Triboulet, who has just died at the age of 56 years, was physician to the Hôpital Trousseau, and, like his father before him, had a great reputation in pediatrics. His death was hastened by the loss of his eldest son, killed as a flying pilot during the war. Along with Lucas-Championnière he was the promoter of the visits of French doctors to England, and had organised medical travel between the two countries. At the last reception to English doctors in France he made a genial president, and many were the friends whom he counted in London.

Feb. 24th.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

A Strike of Clinical Assistants.

THE present conditions of life in this country have resulted in a strike of an unusual character. Hitherto only a small proportion of the hospital medical staffs were paid. The house physician and two or three clinical assistants received a salary on a moderate scale; all other posts were honorary. Their incumbents had a vast opportunity for learning, but were not directly remunerated for their hard work, which was nevertheless essential for the working of the institutions. With the change produced by the catastrophal devaluation of our money, these men could no longer subsist on their mostly very limited means. They demanded a salary as well as the right to obtain for a modest sum their meals at hospitals or clinics. This being refused by the Government, the medical faculty, to whom they applied for help, took the matter up, and after further futile endeavours to come to an understanding the medical strike was proclaimed on Feb. 1st in the clinics. The strike only lasted two hours. The demands were not granted in toto, but they agreed to await further arrangements, having the sympathy of the public, who were anxious to see this question settled in favour of the physicians. This strike is the first instance, in this country, of the adoption of such means to further the economic position of the medical profession.

Increase of Payment for University Appointments.

By an order of the Home Office the fees of the ordinary and extraordinary professors of the Austrian universities have been raised in such a degree as to approach the salaries of other persons in similar standing in civil service. The ordinary professor will now get from 14,000 to 26,000 kronen a year, according to the length of service, besides the extra payment according to the "index" of prices, as published half-yearly by the Board of Commerce, calculated on the average prices of the chief articles of food. At present this extra payment amounts to 21,000 to 36,000 kronen a year in case of the ordinary professor. The extraordinary professor, who has no regular clinic, gets a salary of 10,000 to 18,000 kronen a year, with an additional 14,000 to 24,000 kronen, based upon the index. Part of the fees paid by the students will in future belong to the teacher. A minimum of 600 kronen is guaranteed to the latter, but if the fees exceed the sum of 5000 kronen the teacher gets only half of the surplus. Another feature of the new order is regular payment of the docents, or younger scientists, who render invaluable help by their lectures. They are now to receive 6000 to 12,000 kronen a year. The students now pay three times as much as before for their studies, 6 kronen per hour per week, and in the medical faculty 60 kronen per half year is charged for the use of apparatus. Remembering that the buying value of one English pound sterling is 900 kronen at present here, the proper value of these salaries will be clear.

Financial Difficulties to Scientific Research.

In the Austrian Parliament the Minister of Health, Professor Tandler, pointed out the menace to the existence of scientific institutes owing to the immense rise in the price of materials. Chemistry is worst off now. Reagents and even the simplest apparatus are 50 to 300 times dearer than in 1914, if they are obtainable at all. Students are asked to procure most chemicals at their own expense. Training under such circumstances becomes illusory. In the experimental and sero-pathologic institutes animals are hardly obtainable, for they are more urgently wanted as food. A rabbit costs now nearly as much as a horse did in 1914. The horses, indispensable for producing diphtheria antitoxin, now cost 16,000 to 24,000 kronen each. The food for the horses kept in the Vienna Sero-Therapeutic Institute went up 420 times. The drugs are similarly expensive. A kilo of cocain, costing 300 kronen five years ago, now commands 55,000 kronen; morphia is in much the same case. Ether pro narcosi costs 400 kronen, pure iodine 5,000 kronen. A microscope costs 20,000 kronen, simple scales cost 4000, scientific journals and books cost between 500 and 2000 kronen per year. As the earning capacity of the bulk of the population has not gone up in the same proportion, neither the Government nor the individual student or worker is able to keep abreast with the times.

Influenza and Lethargic Encephalitis.

A new wave of influenza has been noticed in Vienna, milder than the last one in 1918–19. It is characterised by muscular weakness and bronchial affections, with frequent involvement of the accessory cavities of the nose and the middle ear. As the majority of the population seem to be immunised from last year, the epidemic is not very widespread. A series of cases of encephalitis lethargica noticed in the Clinic of Nervous Diseases could not be brought into definite relation with the incidence of influenza. Measles, now very prevalent, shows features nearly related to encephalitis, for the constant desire to sleep is marked, and the children suffer much from after-effects.

Vienna, Feb. 15th.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Farm School for Deficient Children.

AT a meeting of the Budapest Board of Education, called to arouse public sentiment in favour of establishing a farm-training school for mentally deficient children, it was shown that 3 per cent. of the children in the city are imbecile in some degree, up to complete idiocy, making a total of about 800 at present. Other points brought out were that nine-tenths of the mental defectives are uncared-for children who cannot keep up in regular schools, notwithstanding the employment of special rooms for backward children; that these children largely recruit the criminal and pauper classes; that it is cheaper for the State to care for these patients in an institution, which can be made largely self-supporting than to support them as criminals and paupers; and that heredity is the great cause of mental deficiency. It was urged that mentally deficient children be differentiated from simply dull children by modern psychological tests, and that these children be kept for life in a suitable public farm institution, where they would be happier and more useful than at home, and would be prevented from propagating their kind.

The Control of Mineral Waters.

To put an end to the numerous abuses in the sale of the so-called mineral waters the Superior Council of Hygiene has just decided that (1) "mineral water" is a water to which therapeutic properties are ascribed; it should be recognised as such by the Pharmacological Board of the University, authorised by the Government, and exploited under the conditions specified by the official organisation; (2) "natural mineral water" in bottles is labelled so that it may be distinguished from other bottled waters, especially table waters; the employment of descriptive terms implying therapeutic properties is to be forbidden.

Curability of Progressive Paralysis since the Salvarsan Era.

Dr. Kenéz, speaking at the recent conference of Budapest psychiatrists, said he did not think that the recent achievements in serology and the introduction of salvarsan had been of much service in the diagnosis and treatment of progressive paralysis. In fully 24 per cent. of the cases, he said, we may anticipate remissions in the course of the disease during the early stages. A patient entering on a phase of remission should not be reported as "recovered" under the drug that he happened to be taking at the time. If the weight begins to increase, a suspicion of a remittent phase is justified. He further emphasises the point that true syphilitic processes may co-exist with the changes responsible for the paralysis, and consequently benefit will follow as the former subside under specific anti-syphilitic measures.

Punctured Wounds of the Diaphragm.

Dr. Cornea, who had a huge surgical hospital in Innsbruck during 1917 and 1918, reports his experiences with stab wounds of the diaphragm. He attended only 45 similar cases out of 34,627 surgical patients. Only 17 of his cases were without concomitant injury of other internal organs. The wound in the diaphragm was not diagnosed in one-third of the cases; in 7 cases the stab had been received in the fourth and fifth interspace. The danger of diaphragmatic hernia is so great, as also the possibility of unsuspected injury of other organs, that expectant treatment is contra-indicated. In case it proves impossible to suture the wound in the diaphragm, the edges may be sutured to the costal pleura, as Dr. Frey in Vienna has suggested. This prevents hernia and also the danger of secondary infection of the pleural cavity.

Restoration of the Nose.

This same surgeon reports his experiences with rhinoplastic operations; in three of them he made the new nose out of the soldier's fourth finger, as Wolkowitsch advised in 1910. He performed rhinoplastic operations also with other methods, his cases numbering 37. His experiences with the Wolkowitsch method encouraged also other military surgeons to work on this line, as also with the Italian method of rhinoplasty which was applied largely before the war.

Admission of Patients to Public Hospitals in Hungary.

On account of the immense number of unemployed the hospitals are crowded with feigners, who seek food and shelter there. This fact has induced the Board of Public Hygiene, on the recommendation of the Medical Faculty, to limit admission to university hospitals and public hospitals to those whose admission is provided for by statute: students in actual attendance at the University, emergency cases, and patients sent to the hospital by a legally qualified physician. All other persons seeking admission to the hospital must make affidavit that they are not able to pay the ordinary charge of a physician. The abuse of the facilities of the hospital has not been extreme, but has been sufficient to justify this action of the Board of Hygiene.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

New Health Bill and British Medical Association.

THE Health Bill introduced by the Victorian Government has been passed by both legislatures, and the new Commission will be appointed at a quite early date. The Premier has now introduced a clause which renders it possible for medical officers of health appointed under the Act to attend members of lodges and their families, either by agreement made by the Government or by a municipality. There was no discussion of the possible position if the British Medical Association disagreed. Yet the first difficulty in such a provision will be to fill the positions. If this is done in opposition to the Association there are obvious rocks ahead in the way of administration, for it is no easier for a medical man than anyone else to serve two masters, and the Association will not allow its members to accept positions unless at its own rates. The members of the Returned Medical Officers' Association have also signified their intention of not applying for these positions.

Mask Wearing in Sydney.

When the compulsory wearing of masks as a protection against influenza was first introduced in Sydney, Dr. Fox, a practitioner at Glebe, refused to comply and was arrested. He subsequently entered an action against the authorities, who had refused to proceed with their own action. He was awarded £250 damages.

Curious Double Fatality.

An unusual occurrence has occupied the public attention in Melbourne. A female patient went to a suburban dentist to have a decayed tooth extracted. An excited call was made by the operator on the telephone for medical assistance as the patient had collapsed. A medical man was at once in attendance, but found on arrival that the patient, a young widow, aged 32, was dead, and the dentist, who was lying in another room at the point of death, died in a few minutes. The autopsy showed that the patient had apparently died of heart failure following the injection of a local anæsthetic into the gum around a tooth, which was not extracted. The surroundings indicated that the dentist had made attempts to revive the woman and then in a sudden paroxysm of alarm had himself taken poison in the shape of a solution of cyanide of potassium. A doctor who was called stated that the dentist had been under treatment for some weeks suffering from nervous depression.

Radium Burn.

Dr. L. J. Clendinnen, a well-known specialist in Melbourne in radiology, was recently sued for damages as the result of the application of radium. The patient was a young women employed as a clerk who suffered from a corn on the sole of one foot. She consulted a surgeon, who advised radium should be tried. Radium was applied in a private hospital by Dr. Clendinnen. Thereafter the foot became painful and ulcerated, and it was alleged that the doctor did not see it again, and declined to visit her when requested. Several other practitioners were consulted, and the patient was laid up for some months. For the defence numerous medical men gave evidence that in their opinion the radium had been properly applied, and there was no permanent damage resulting to the foot. The jury gave a verdict for the plaintiff, and awarded £250 damages. Dr. Clendinnen was subsequently tendered an expression of sympathy by many of his colleagues.

Professorial Chairs.

Dr. A. E. Mills has been appointed to the professorship of medicine in the University of Sydney. The vacancy as professor of pathology in the University of Adelaide created by the retirement of Dr. A. Watson has been filled by the appointment of Dr. J. Burton Cleland, who resigns his post as chief micro-biologist to the New South Wales Government. Both the new professors are graduates of the University of Sydney.

Commonwealth Public Health Service.

It is announced that the Federal Government intends to proceed with the establishment of a Federal Health Department in addition to its quarantine activities. All the States have approved the proposal, but it is yet doubtful what legislative powers are required. At present it is not likely that more will be attempted than the encouragement of research and the perfecting of statistical and other information between the existing State Departments.

Melbourne, Jan. 13th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

India and Yellow Fever.

THE decision of the Government of India to appoint a committee to report on the measures which may be necessary to prevent the introduction of yellow fever into that country directs attention once more to the importance of creating a strong Department of Health. The problem would have been taken in hand long ago if a well-organised department of public health had existed. Seven years ago an official report was published which opened with the following statement: "Yellow fever has not appeared in India, but the abundant presence of the mosquito *Stegomyia fasciata*, which transmits it, the susceptibility of the population, and general conditions in the chief seaports are very favourable to its existence and spread, and it is believed that the introduction of the virus would be followed by devastating epidemics which would be exceedingly difficult to control." It requires no special knowledge to grasp the significance of this announcement, which came ten years after Sir Patrick Manson had directed attention to the possibility that the opening of the Panama Canal might eventually lead to the introduction of yellow fever into Asia.

General Health of the United Provinces.

The severe epidemic of influenza last year had an injurious influence on the general health of the population, and greatly interfered with the normal activities of the medical and sanitary authorities. In the United Provinces the latest provincial report on vaccination shows that influenza was mainly responsible for a decrease of 298,997 in the number of primary operations. In the districts wherever the disease broke out in an epidemic form vaccination had to be temporarily stopped, and vaccinators were supplied with medicines and employed in perambulating medical work. Also a considerable proportion of children were rendered unfit for vaccination by the disease. Plague, cholera, and relapsing fever must also be held partly responsible for the decrease in vaccination. Revaccination returns showed an increase of 34,176 over the previous year's figures, due to the large number of operations following various outbreaks.

War Gratuity of Civil Surgeons.

It is notified that, in the case of officers of the Indian Medical Service, service in civil employment will not count as service qualifying for the grant of war gratuity.

Red Cross Activities in Afghan Operations.

In a report to the Commander-in-Chief the chairman of the Indian Red Cross states that the Red Cross started operations as soon as the news of the outbreak of hostilities was received, and issued orders for supplies on a large scale to be sent up from the Bombay depôt. It also took steps to make available at once supplies in the depôts in Lahore, which were equipped on a 500-bed basis, and Rawalpindi, where the stores were on a 300-bed basis. Depôts were opened at Rawalpindi, Peshawar, Kohat, Bannu, and Quetta, and the Red Cross authorities were able at an early date to appoint

Assistant Commissioners to the charge of these depôts. In addition, subdepôts were opened at Tank and Dera Ismail Khan. For the Murree hospitals the Red Cross representative was Lady Kemball, who undertook all work in connexion with these hospitals, and established a separate depôt at Kuldana. The system pursued by the Red Cross was to instruct its Assistant Commissioners to make themselves acquainted with the needs of the hospitals, field ambulances, and transport stations in their areas, and to forward to Simla an indent of articles necessary to keep their depôts supplied with materials required. Headquarters provided them with cash for local purchases. Indents from hospitals were, as a rule, countersigned by the A.D.M.S., but this rule was never enforced with any rigidity, and very large supplies were made on the direct request of the officers commanding hospitals.

Mortality from Influenza.

There has been an increase in the mortality from influenza in Karachi, and also in Bihar and Orissa. In Bengal and Madras the mortality is diminishing. In other parts of India the disease shows signs of spreading, and the cases appear to be of a mild type.

URBAN VITAL STATISTICS.

(Week ended Feb. 21st, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had increased from 15·3 to 17·4 in the four preceding weeks, fell to 16·8 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the annual rate was 17·9, or 0·5 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 6·9 in Darlington, 7·0 in Eastbourne, and 8·0 in Barrow-in-Furness, to 23·9 in Cambridge, 24·8 in Hastings, and 27·3 in Bootle. The principal epidemic diseases caused 408 deaths, which corresponded to an annual rate of 1·3 per 1000, and comprised 158 from measles, 109 from whooping-cough, 71 from diphtheria, 53 from infantile diarrhœa, 11 from scarlet fever, 4 from enteric fever, and 2 from small-pox. Measles caused a death-rate of 1·6 in Leeds, 1·8 in Lincoln, 2·3 in St. Helens, 2·8 in Hull, and 3·8 in Gloucester and in Wigan; and whooping-cough of 1·6 in Birkenhead and 1·7 in Edmonton. The fatal cases of small-pox belonged to Poplar and East Ham respectively. The deaths from influenza, which had been 66, 98, and 109 in the three preceding weeks, further rose to 161, and included 37 in London, 19 in Birmingham, 15 in Liverpool, and 7 each in Wallasey, Manchester, and Leeds. There were 2415 cases of scarlet fever, 2000 of diphtheria, and 2 of small-pox under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2459, 2010, and 3 respectively at the end of the previous week. The causes of 47 deaths in the 96 towns were uncertified, of which 16 were registered in Birmingham, 6 in South Shields, 5 in Liverpool, and 4 in London.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at 2,400,000 persons, the annual rate of mortality, which had been 15·9, 14·7, and 14·7 in the three preceding weeks, further fell to 14·2 per 1000. The 290 deaths in Glasgow corresponded to an annual rate of 13·6 per 1000, and included 4 from measles, 3 from whooping-cough, and 2 each from diphtheria and infantile diarrhœa. The 84 deaths in Edinburgh were equal to a rate of 12·8 per 1000, and included 2 fatal cases of diphtheria.

Irish Towns.—The 131 deaths in Dublin corresponded to an annual rate of 16·5, or 1·0 per 1000 below that recorded in the previous week, and included 3 each from measles and infantile diarrhœa, 2 from whooping-cough, and 1 each from scarlet fever and diphtheria. The 144 deaths in Belfast were equal to a rate of 18·2 per 1000, and included 9 from measles, 6 from whooping-cough, 2 each from enteric fever and scarlet fever, and 1 from infantile diarrhœa.

THE SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The Honorary Fellowship of the Society of Medical Officers of Health has been conferred on Brigadier-General Sir William Heaton Horrocks "in recognition of his invaluable services as chief of the Army Sanitary Department throughout the Great War," and on Dr. Henry Edward Armstrong, formerly medical officer of health for Newcastle-upon-Tyne, "for his long and distinguished services in connexion with public health administration and the advancement of sanitary science."

Correspondence.

"Audi alteram partem."

MEMORIAL TO OFFICERS AND MEN OF THE R.A.M.C. WHO FELL IN THE WAR.

To the Editor of THE LANCET.

SIR,—May I venture to bring to the notice of any of your readers, who may be unaware of the active prosecution of the above project, the following particulars.

A Committee representing every branch of the R.A.M.C. has been formed under the presidency of the Director-General Medical Services. This Committee has decided to erect a memorial bearing the names of all officers and men who fell during the war, and place this upon a prominent site in London, and if funds permit to erect replicas in Edinburgh and Dublin. The monument will stand in honour of the entire profession, and the project should also appeal to the many who received help at its hands in the hour of strenuous need. A sum of some £10,000 has been already collected by army commands, but it is estimated that at least £30,000 will be required if the monument is to be made worthy of the men to whose honour it is to be dedicated.

Subscriptions may be sent to army commands, or direct to the treasurers of the fund, Messrs. Holt and Co., 3, Whitehall-place, S.W. 1, marked R.A.M.C. War Memorial Fund.—I am, Sir, yours faithfully,

Wilton-place, S.W., Feb. 20th, 1920. G. H. MAKINS.

IS THERE A PARA-SCARLET FEVER?

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 21st Dr. Charles Box gives reasons for his belief that a certain series of cases of scarlet fever were not cases of rubella, and he says I asked him for these reasons. If he will be so good as to look at my letter again he will see that I did not do so, but that I did ask him to indicate the points which made him certain that none of them was rubella. His letter in your issue of Jan. 31st not only stated his belief but asserted his certainty. Dr. Box admits he would be the last to assert that the differentiation of mild scarlet fever from rubella is always possible, and I do not suppose he intends to maintain that it was possible in each one of the series referred to. Yet in referring to rubella he goes so far as to say that not a single case of this disease occurred in his wards. Now is it possible to say this and yet admit inability (as we all do) to differentiate in some instances?

Dr. Goodall's statement that rubella has not been prevalent in London lately is in no part answer to my query, as Dr. Box seems to consider; and it by no means follows that a case of rubella admitted into a scarlet fever ward results in an outbreak of that disease, though it often does. It is true rubella has not been epidemic of late in London, but I take it Dr. Goodall is only speaking of his own hospital when, in referring to outbreaks of rubella in wards, he says: "Such untoward results are not happening." As a matter of fact, I have had several wards in quarantine for rubella this winter, and have one now. Dr. Box's additional arguments in no way show that not one of his cases was rubella. I am, Sir, yours faithfully,

FREDERIC THOMSON.

North-Eastern Hospital, Tottenham, N., Feb. 21st, 1920.

To the Editor of THE LANCET.

SIR,—In connexion with this question raised by Dr. C. R. Box in THE LANCET of Jan. 31st the following facts may be of interest. Amongst 148 cases admitted as scarlet fever to the Borough Isolation Hospital, Ealing, from June, 1919, to January, 1920, inclusive, there have been eight cases which relapsed. The relapses all occurred amongst the 32 cases admitted during November. The particulars of these cases are set out in the following table.

No. of case.	Age.	Sex.	Admitted.	Relapsed.	Interval.
1	7	M.	Nov. 2nd.	Dec. 3rd.	31 days.
2	32	F.	,, 4th.	Nov. 24th.	20 ,,
3	3	M.	,, 10th.	,, 28th.	18 ,,
4	6	M.	,, 11th.	Dec. 18th.	37 ,,
5	6	M.	,, 11th.	Nov. 18th.	7 ,,
6	7	M.	,, 13th.	Dec. 29th.	46 ,,
7	5	M.	,, 17th.	,, 21st.	34 ,,
8	6	F.	,, 28th.	,, 23rd.	25 ,,

The average daily number of cases of scarlet fever in hospital during November was 43, and during December 32, nursed by the same staff in two wards served by a common kitchen.—I am, Sir, yours faithfully,

Ealing, W., Feb. 23rd, 1920. R. P. GARROW.

THE INFECTIVITY OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I think I should answer the letters written to THE LANCET since the publication of my lecture on Pulmonary and other Forms of Tuberculosis in your issue of Jan. 24th. These letters were written by Dr. E. Ward, Dr. Oscar M. Holden, and Dr. J. Fairley, who are, or have been, tuberculosis officers. I will not endeavour to answer all their criticisms.

With regard to Dr. Ward's letter, I am glad to find that both he, as well as the other two medical men, agree that we have failed in our treatment of tuberculosis. The sanatoriums and sanatorium methods are not doing what they were said to do. Dr. Ward complains, as each of the other two writers has complained, that not enough is done to separate infective people from others who appear to be healthy. I agree most thoroughly that, if it was proved up to the hilt that the infection by the tubercle bacillus in all cases, or in the majority of cases, or in a goodly number of cases, could be originated at any stage in life after childhood by infection from a tuberculous subject—such as is the case in measles, whooping-cough, and diphtheria—then segregation should be carried out, always remembering that the consideration shown for the infected subject, as sketched out by Dr. Fairley, is duly attended to. But, feeling as I do that there are so many good arguments for the theory that the only infection with tubercle bacillus which really matters is the one contracted in childhood, I hesitate to be as optimistic, as these gentlemen are, that segregation will stamp out tuberculosis; and, for this reason, that I think there are are so many symptomless, and even signless, tuberculous "carriers" who could be potential, and actual, infective agents that our children would still be infected. I will not cross lances with Dr. Ward as to which is the more serious infection, tuberculosis of the respiratory tract or catarrh of the respiratory tract. I have expressed my belief in the theory that the accessory catarrhal infections are the main causes of the signs and symptoms I meet with in the consumptive. I am glad Dr. Ward agrees that there are cases which appear clinically to be tuberculosis of the lungs, or consumption, in which the tubercle bacilli are repeatedly absent from the sputum; but, until Dr. Ward, or some other worker, establishes as a fact his hypothesis of the existence of an unrecognised form of the tubercle bacillus, I think such cases should not be treated as if they were due to tuberculous infection.

Dr. Holden will forgive me for tilting at the cocksure way in which he prophesies that segregation would render tuberculosis in a generation as uncommon as leprosy. I would ask him to use his efforts to substantiate that theory by direct experiment before he uses the weight of his opinion in holding out before the public still another cure for tuberculosis.

Dr. Fairley asked me if it is my considered opinion that the adoption of prophylactic vaccination against tuberculosis and catarrhal infections would lower the tuberculosis death-rate, and my answer is that, arguing on the analogy of what had been done to prevent typhoid fever in the army, I say that I consider inquiry by experiment should be made in this direction. I do not advocate it for application in practice until favourable experiments are carried out. I must counter one remark of Dr. Fairley's. He says that tuberculin tests enable us to find out infected cows. Surely in these days it is not necessary to remind Dr. Fairley that cattle may be tuberculous and yet give no tuberculin reaction, so that when we "cleaned up our herds" we should still be left with cattle which were capable of infecting our children. Such an example of the difficulties met with in preventing the spread of tuberculosis is only one of the many which I fear beset us in this difficult subject.

I am, Sir, yours faithfully,

Harley-street, W., Feb. 23rd, 1920. H. BATTY SHAW.

THE INTERNATIONAL CONGRESS OF MONACO.

To the Editor of THE LANCET.

SIR,—Allow me to draw the attention of your readers to the special interest of the forthcoming International Congress of Monaco. The Congress will open on April 15th, under the presidency of H.S.H. Prince Albert I. of Monaco. It amalgamates the following scientific congresses: (1) Medical Hydrology and Geology; (2) Hygiene and Climatology; (3) Spas and Thalassotherapy. It is expected to last ten days.

It seems futile to insist on the scientific interest of these various congresses, but I should like to point out the national interest of this occasion for the health resorts of Great Britain. The Congress is exclusively open to the Allies. So far as the benefit of a cure in health resorts is derived from the complete change in the patient's habits and surroundings, is it not time for Great Britain to cater for those who, previous to the war, used to flock to Central Europe?

The organising committee has been working, as might be expected, under difficult circumstances; nevertheless, special facilities as regards travelling and hotel accommodation will, it is hoped, help to make this gathering a success.

For information apply to Dr. C. F. Sonntag, secretary of the Balneological Section of the Royal Society of Medicine, Zoological Society, Regent's Park, N.W.

I am, Sir, yours faithfully,
GUSTAVE MONOD, M.D., M.R.C.P.,
Vichy, Feb. 18th, 1920. Secretary of the Organising Committee.

ANÆSTHESIA IN THROAT AND NOSE OPERATIONS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Feb. 21st you publish Dr. Felix Rood's admirable paper on Anæsthesia in Throat and Nose Operations. In spite of the fact that there are still a few advocates of chloroform, the case against this anæsthetic was well established, and the only conclusion possible is that there is a very general agreement that ether is preferable. It is evident that the whole difficulty originates from the fact that there is blood in the neighbourhood of the glottis, and yet neither in the opening paper nor in the subsequent discussion was there any mention made of any attempt to solve the problem by an efficient device for removal of the blood.

During a recent visit to the throat clinics in the United States I was much struck by the usefulness of an apparatus for aspiration of blood which is in general use there. This blood evacuator is made in a compact and portable form, and consists of a motor-driven combination pressure and suction apparatus, by means of which it is possible completely to evacuate the blood from the throat, while at the same time delivering a regulated stream of ether vapour. I have now used it in a large number of cases to the entire satisfaction of the anæsthetist and myself, and am convinced that no method which does not embody this principle of removal of blood by suction can secure such a quiet field of operation and opportunity for leisurely performance of pharyngeal operations. It obviates the repeated sponging which is one of the chief difficulties of the anæsthetist, the sole sponging necessary being the use of one sterile swab for each tonsil fossa. There is no sickness, and the careful examination of the fossa, which is so essential, is made quite easy. The total absence of congestion makes this method ideal for such cases as pericarditis and exophthalmic goitre, and any of those chronic infective conditions which so frequently need tonsillectomy. Many such cases are included in my list, and the contrast has been very striking when compared to other methods.

The apparatus was designed by Dr. Yankauer, of New York.

I am, Sir, yours faithfully,
A. M. ZAMORA, M.C.Camb., F.R.C.S.Eng.
Welbeck-street, W., Feb. 23rd, 1920.

THE LESSONS OF STATISTICAL METHODS.

To the Editor of THE LANCET.

SIR,—Dr. H. Batty Shaw's lecture in THE LANCET of Jan. 24th on Pulmonary and Other Forms of Tuberculosis has brought to my mind a subject which I have thought a good deal about and which I may call the statistical evaluation of different lines of treatment in disease. I am not acquainted with any work, either of a private or official nature, which effects this—a most important subject for all who have to advise patients on the probable best line of treatment to adopt.

I can make clear what I mean, I think, by a hypothetical case of any common disease. A patient consults me with, say, cancer of the breast involving the axillary glands, and I, as a general practitioner, get a surgeon's advice and he advises an operation. I recommend my patient to follow the surgeon's advice, but at the same time am not quite sure in my mind that the result will be a satisfactory one. But what am I to do? All the surgeons say that the evidence is overwhelming for operative measures; but where can I get evidence of, say, 5000 operations for breast cancer and the duration of life, freedom from pain, absence of recurrence and for how long, and so forth? Can I get evidence of 5000 breast cancers treated by any one other method and their results?

The essence of this idea lies in the following up of all cases of illness, however trivial, and the treatment adopted over a considerable number of years; in fact, it means a medical history-sheet for every member of the community, which would ultimately have to be classified, and a group formed for a period of five years or more or less, from which one would get some idea as to some outstanding therapeutic measure of any real value.

What are therapeutics at the present day? Frequently individual fancies of the practitioner based on his own, necessarily very small, experience, and the statements, also usually the experiences of an individual, that he reads in books on therapeutics. We should all like to be able to get statistical evidence of, say 100,000 cases of tuberculosis, which would go far to convince us that the tuberculosis of the adult was an "inside" infection from an old arrested infection of childhood, or that it was an "outside," say inhalation, infection, from an infected dwelling, as it would make an enormous difference to our methods of combating the disease.

I once was discussing some operative procedure with a friend who had been a house surgeon in a large clinical hospital and left this appointment with all the enthusiasm of youth for this operative procedure, but his enthusiasm was sadly damped by a period of residence in a workhouse infirmary in the neighbourhood shortly after when he saw several of these surgical triumphs coming in to die. Here we have individual experience of the smallest degree, but it is going to influence that practitioner in his future practice. Would it not be an enormous advantage if a thousand or ten thousand cases of that disease, their duration, and general course under the operation in question and alternative methods were available at a central clearing-house where the practitioner could get information from.

It will naturally be asked how is this colossal amount of information to be obtained. The present National Insurance system is a ready-made channel for working through, and with regard to that system I am of opinion that a large amount of the trivial work performed by the general practitioner could be performed by nurses, and a reduced quantity of a better-class and better-paid-for work could then be performed by the practitioner.

It is, perhaps, pointing to all medical service being a question of State service, but whether that be so or not I am quite convinced that it is only by the comparative valuation of therapeutic measures taken in as large a number of cases as possible and their results watched and estimated over as long a period as possible, that we shall emerge from, shall I say, the empiricism of the physician and the individualism of the surgeon.

I am, Sir, yours faithfully,
Charing, Kent, Feb. 14th, 1920. H. E. LITTLEDALE, M.D.

THE DIAGNOSIS OF MALARIA.

To the Editor of THE LANCET.

SIR,—In the Experiences of Malaria in the Egyptian Expeditionary Force published in THE LANCET of Jan. 10th Mr. Philip Manson-Bahr rightly insists on the necessity of early microscopic diagnosis in malaria. The reason given is that in its absence clinicians are liable to make mistakes. Three cases diagnosed clinically as sunstroke were subsequently found, by microscopic examination, to have been malignant malaria; five cases of dysentery were subsequently diagnosed malarial enteritis; cases diagnosed clinically as relapsing and enteric fevers were subsequently, by microscopic diagnosis, found to have been malarial relapses; and cases diagnosed clinically as epidemic influenza, which was prevalent, were subsequently diagnosed by microscopic examination as malignant malaria. The small number of clinical mistakes discovered in the sick of such a large force reflects, I think, great credit on the medical officers of the force. Such mistakes are not always avoidable under the circumstances attending a rapid advance of a large force in the field.

In Palestine malarial fever is very prevalent. Masterman, who investigated malaria there before the war, remarked that the verdict of the microscope upsets all ideas of clinical experience. Parasites are found swarming in the blood of some, especially children, who exhibit no rise of body temperature, and who are to all appearance in good health, whilst in others suffering from what is clinically a typical malarial fever not even one parasite can be found in the blood. Hence it is possible that the subsequent discovery of parasites in a patient's blood does not mean that the original clinical diagnosis of another disease must necessarily have been an error. Also the failure to find parasites in the blood during the first few days of a primary attack of malaria does not exclude the possibility of the disease being malaria. The absence of parasites from the blood during the first three days of the fever is well illustrated in the original report of Manson's famous experiment in London, as published in THE LANCET of Sept. 29th, 1900, p. 923. Mosquitoes fed on malarial subjects in Rome had been brought to London and there allowed to bite two healthy young men. Of the two bitten men, the history of only one is related in the report. He had been bitten by about 55 mosquitoes on the hands and arms. This produced considerable irritation of the skin, persisting for two days, and subsequently malarial fever developed. During the first three days of the fever the body temperature varied between 100·4° and 103·6° F., but not even one parasite could be found in the blood, although repeatedly searched for. On the morning of the fourth day of the fever body temperature had fallen to 98·4°, and rose again to 102·8°. Repeated microscopic examination of the blood revealed only one doubtful half-grown tertian parasite. On the fifth day of the fever the morning body temperature was 99°. Several half-grown parasites, one gamete, and two pigmented leucocytes were found in the blood in the first film examined. During the day many tertian parasites were found, and the body temperature rose to 103°. On the sixth day of the experiment the body temperature in the morning had fallen to 97°, and did not again rise. A few three-quarter grown tertian parasites were found in the blood.

It is seen, then, that although it has been computed that one-quarter of a billion parasites must be present to produce fever, not even one parasite could be found in the blood during the first three days of the fever, whilst during the last three days, as the fever subsided, parasites were found. This absence of parasites from the blood during the first few days of a primary attack of malaria, such as in the experiment, and their appearance in the blood later was doubtless the reason why some who, when Laveran announced he had discovered parasites in malarial blood which were the cause of the fever, asserted that the bodies he discovered were not parasites, but what are now called pseudo-parasites—i.e., blood corpuscles changed in appearance, so that they resemble Laveran's bodies. Their late appearance in the blood was given as reason for regarding them as an effect, and not the cause of the fever.

When, as we have seen, the best expert microscopists failed to discover parasites in the blood during the first three days of the experiment in a quiet home in London, it is too much to expect that microscopic diagnosis would be more successful under the unfavourable circumstances attending the rapid advance of a large force in the field as in Palestine.

I am, Sir, yours faithfully,

Leeds, Feb. 24th, 1920. MATHEW D. O'CONNELL, M.D.

PREVENTION OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—I have followed with interest the discussion on the prevention and treatment of venereal disease, and the attitude with regard to the subject taken by the National Council for Combating Venereal Diseases, the Society for the Prevention of Venereal Diseases, and the proposals for dealing with these diseases that have been brought before the public, notably by the *Times*. The "Memorandum of the Policy of the Medical Women's Federation," as reported in THE LANCET of Feb. 14th, adds another expression of opinion with which I do not think all medical women will agree, in so far that it does not appear to grapple sufficiently with the preventive side of the question from the medical point of view. It seems most regrettable that a controversy should be carried on when a combined and concentrated effort is so urgently needed to meet and to deal with what is acknowledged to be a scourge and a source of national weakness, and I feel inclined to ask. Have we not a dual responsibility with regard to this matter—namely, that of citizens, and that of medical practitioners responsible for the health of the nation? As citizens we must further by every means in our power all endeavours made to combat the evil by legislation, by social effort, by education, and by religious instruction, and the last by no means the least, for it requires a greater incentive than the fear of results to deter most men or women from sin—and fornication is sin.

Having, I hope, guarded myself from misunderstanding and made my position clear, it appears to me that as doctors we must face the fact that a certain proportion of individuals, either from force of temptation, heedlessness, or of deliberate choice do, and will, run the risk of infection, and for those provision must be made as far as possible to prevent the development of disease in them, and the carrying of disease by them, not so much perhaps for their own sakes, as in defence of and for the sake of the innocent women and children who may immediately or later become infected by them. The far-reaching effects of congenital syphilis have not even yet been fully realised.

The controversy seems to centre round a most unfortunate phrase, "Prophylactic Packets." No one in these days can object to personal hygiene, and it would seem only reasonable to teach the need for immediate disinfection after illicit intercourse, where unquestionably a possible risk of infection is always incurred, and to ask this is no more than to ask—what is acknowledged to be a duty as a citizen—that after contact with any other infectious and possibly much less dangerous disease precautions against infection should be taken. In view of the evidence given by witnesses before the Interdepartmental Committee, and statements made by those in a position to know, it appears to be established that early disinfection does minimise the development of these diseases. This being so, if the practice of disinfection were adopted by men, even though it were not efficiently carried out in every case, it would surely go a long way to prevent the spread of disease, to save misery in families, and the ill-health of which we see so much in young married women.

Early preventive treatment for women cannot, for obvious reasons, be advocated in the same way. It is now comparatively easy to recommend treatment to married women and to unmarried mothers who have been infected. But the class of women and young girls who, for the sake of argument, may be regarded as the primary source of infection, present a much more difficult problem. Fortunately, the greater number of them do not become mothers. When we consider the social conditions of the majority of the young girls who lead more or less irregular lives, one realises how impossible it is for them, even when the disease has been diagnosed, to carry out directions such as those given in Forms V. 6 and V. 7, published by the Local Government Board, regarding precautions to be taken by those suffering from syphilis and gonorrhœa as regards the "risk of infecting others." As well might we expect a patient suffering from scarlet fever to be satisfactorily treated in a house of one or two rooms inhabited by a large family. Most of those girls who are spreading disease, and who may be a greater source of danger than the older women, are living at home or in lodgings, and are in daily employment; they may be working in dairies, or employed as waitresses, or otherwise handling food, or even be in situations and have charge of young children. To deal satisfactorily with this class, much greater provision for indoor treatment must be provided than is at present available, and a much more elastic provision for admission must be made, even if it entail something of the nature of reception wards, so that any woman who applies for treatment or shelter at any hour of the day or night can be admitted. If efficient help were available when sought for, it would induce many, when they fear they have become infected, or that they have contracted disease, to seek advice, and would be taken advantage of according as to how the benefit was administered. If efficient help is not given when sought for, the probability is that the women may not return.

Another difficulty which presents itself is that a number of those who seek advice discontinue treatment before the acutely infectious stage is past. The consensus of opinion is against notification, but I am inclined to the belief that if some form of confidential notification could be introduced, applicable equally to men as to women, and only to be applied to those cases that are in an acutely infectious stage, it would be of service in ensuring continuity of treatment. Ophthalmia neonatorum is now a notifiable disease, and there is no outcry as to its injustice, although it indicates, to those who know what it means, the nature of the disease and the probable source of infection. Before, however, this measure can be whole-heartedly advocated, time must be given to allow of evidence being collected as to the efficient working of venereal disease clinics and the results attained in the reduction of venereal disease.

I am, Sir, yours faithfully,

LAURA STEWART SANDEMAN, M.D.

Aberdeen, Feb. 19th, 1920.

GREAT NORTHERN CENTRAL HOSPITAL.—In order to meet the growing demands of North London the Committee of Management of the Great Northern Central Hospital, Holloway-road, N., are providing, from March 1st, a special department for diseases of children and child-welfare consultative centre. There will be two sections—medical and surgical—and the session will be held on Monday afternoons at 2.30. This department is intended for children under 12 years of age.

Medical News.

Smoke Abatement.—The Minister of Health has appointed a Committee to consider the present state of the law as regards the pollution of the air by smoke and other noxious vapours and to advise what steps are desirable and practicable to diminish the evils still arising from such pollution. A Departmental Committee was appointed by Mr. Herbert Samuel in 1914 to inquire into this subject and it had made some progress in taking evidence when the war broke out and its proceedings were discontinued. Lord Newton will be chairman of the new Committee and the other members are Captain Hamilton Benn, M.P.; Professor J. B. Cohen, Leeds University; Mr. W. S. Curphey, Chief Alkali Inspector, Ministry of Health; Sir John Lithiby, late legal adviser to the Local Government Board; Mr. J. F. MacCabe, Local Government Board, Ireland; Mrs. Gilbert Samuel; Mr. E. D. Simon, Manchester City Council; Bailie W. B. Smith, Glasgow City Council; and Mr. F. J. Willis; Chief Assistant Secretary, Ministry of Health. Mr. E. C. H. Salmon, of the Ministry of Health, will act as secretary to the Committee, and any communication should be addressed to him at the Ministry of Health, Whitehall, S.W.1.

Conjoint Examining Board: Diploma in Tropical Medicine and Hygiene.—New regulations for this diploma were adopted by the Royal College of Surgeons on Feb. 12th. They require only a three months' course of instruction in tropical medicine at a recognised school instead of the longer course formerly prescribed. The synopsis of the examination has been modified and now runs as follows:—

1. The methods of examination of tissues, blood, secretions, excretions, parasites, and others organisms in relation to tropical medicine. The characters and life-history of protozoa, helminths, arthropoda, fungi, bacteria, and other organisms in relation to tropical diseases.
2. Medicine in relation to tropical diseases.
3. Hygiene of the tropics in relation to climate, race, food, water, soil, and waste matter.
4. Hygiene of the tropics in relation to towns, buildings, plantations, irrigation, and shipping.
5. Reclaiming of swamps and low-lying lands.
6. Sanitary measures dealing with communicable tropical diseases.

The next examination will be held on April 26th, and candidates who have complied with the conditions of the new regulations will then be admitted.

Royal Institution.—On Tuesday next (March 2nd), at 3 o'clock, Professor Arthur Keith begins a course of four lectures at the Royal Institution on British Ethnology: the Invaders of England; and on Thursday (March 4th) Lieutenant-Colonel Gold delivers the first of two lectures on the Upper Air. Sir John Cadman's postponed lectures on (1) Modern Development of the Miner's Safety Lamp, and (2) Petroleum and the War, will be delivered on Monday and Wednesday, March 8th and 10th. The Friday evening discourse on March 5th will be delivered by the Hon. J. W. Fortescue on Military History, and on March 12th by W. W. Rouse Ball on String Figures.

Instruction in Venereal Diseases at St. Bartholomew's Hospital Clinic.—A second post-graduate course of instruction in the diagnosis and treatment of venereal disease is being arranged by Mr. K. M. Walker at St. Bartholomew's Hospital Clinic, Golden-lane, E.C., established by the Corporation of London. The course will be held on Thursday afternoons, at 5.30, commencing on Thursday, March 4th. The beds attached to the clinic are available for the reception and study of suitable cases in addition to work in the out-patient department. There are still a certain number of vacancies. Any medical practitioner wishing to attend is invited to send his name to the Secretary, National Council for Combating Venereal Diseases, 81, Avenue Chambers, Southampton-row, W.C.1.

Literary Intelligence.—Messrs. Masson et Cie. announce the reappearance of the *Revue de la Tuberculose*, discontinued since 1917, under the editorship of Dr. Courcoux and a managing committee of 26 distinguished colleagues. It is the official organ of the Œuvre de la Tuberculose, and appears bi-monthly. Annual subscription in France 30 frs., abroad 35 frs.—A new monthly journal entitled *Gynécologie et Obstétrique* is also appearing, beginning in February, and replacing three journals which may briefly be described as the *Revue Pozzi*, the *Archives*, and the *Annales*. The first number contains 95 pages of original matter alone, with a number of abstracts. The annual subscription is 40 frs. (France), 50 frs. (abroad).—The useful journal of reference entitled *Folia Hæmatologica*, founded by Professor A. Pappenheim, is to be continued under the joint editorship of Dr. O. Nägeli in Zurich and Dr. H. Hirschfeld in Berlin.

Sir Bertrand Dawson has taken the title of Baron Dawson of Penn in the county of Buckinghamshire.

At the sitting of the Vienna Medical Society held on Jan. 30th, Professor F. K. Wenckebach paid a warm tribute to the memory of Sir William Osler.

Erratum.—In commenting last week upon Dr. Murray Leslie's lectures, delivered at the Institute of Hygiene, we stated that the audience consisted of the members of the Royal Sanitary Institute.

Presentation to a Medical Man.—Dr. F. H. Haynes, J.P., consulting physician to the Warneford Hospital, Leamington, after completing 50 years as a member of the staff of the hospital, has been presented with an illuminated address and invited to sit for his portrait in oils.

A Centenarian.—The death occurred at Worthing on Feb. 20th of Miss Emmeline Draper, who on Nov. 2nd last attained the great age of 104. Her sight failed her a few years ago, but except for this her senses were wonderfully acute. She was a native of Ostend, where her father, a surgeon in the old 78th Highlanders, had formerly been stationed.

No. 34 (the Welsh) General Hospital and the Welsh Hospital, Netley.—It is proposed to hold a reunion dinner for all ranks (men and women) in London towards the end of April. Those wishing to attend should notify Mr. R. L. Mackenzie-Wallace, 55, Townshend-road, London, N.W.8, or Mr. E. J. August, 51, Etchingham Park-road, London, N.3, before March 12th.

No. 3 Casualty Clearing Station.—It is proposed to hold a reunion dinner of officers who served with this unit on Saturday evening, March 20th, at 7.30 P.M. Officers desirous of being present should communicate with Major A. D. Stirling, D.S.O., R.A.M.C., War Office, Cornwall House, Stamford-street, London, S.E.1, as early as possible. Officers who were attached to the unit will also be welcome.

King's College, London: Old Students' Association.—There is a strong movement on foot for forming a properly constituted Old Students' Association at King's College, London. A committee was lately formed which has drawn up a provisional constitution, and a general meeting has been called for March 4th at 6 P.M. at the College in order to ratify it. It has been possible to send notices of this meeting only to those old students whose names are on the Register, but it is hoped that the meeting will be made widely known, and that as many old students as possible will be there.

Diet and the Prevention of Influenza.—A Memorandum published by the Food (War) Committee of the Royal Society states that wrong methods of cooking impair the value of antiscorbutic vitamines, and urges that soda shall on no account be used, and that vegetables shall be cooked rapidly and for as short a time as possible. The Council of the Bread and Food Reform League and other signatories are petitioning the Minister of Health that the attention of the people shall be directed to these subjects, thus enabling them the better to resist the infection of influenza and other epidemics.

The Dublin "Curfew Order."—An order signed by the competent military authority last week requires all persons within the Dublin Metropolitan Police District to remain indoors between 12 midnight and 5 A.M., unless provided with a written permit. It is promised that permits will be granted to clergymen, medical practitioners, and nurses engaged on urgent duties. Any person abroad within the hours mentioned is warned to halt and obey any order given him when challenged by any policeman, officer, non-commissioned officer, or soldier on duty. It is to be hoped that this order will be carried out with due consideration for the care of the sick and the safety of their ministrants.

Bangor Nursing Society.—At the annual meeting of this society on Feb. 16th Sir John Byers gave an address on "A Ministry of Health," explaining its origin, composition, and functions, and its relation to Ireland. He showed how far Ireland was behind Scotland and England in public health administration. There was no medical inspection of schools nor school medical clinics, which had existed in these other countries for 10 years; the insurance scheme in Ireland was without medical benefits; there were no county medical officers of health; there were no medical research committees to help in the solution of difficult medical problems. Far too much of public health legislation in the past was of a permissive nature, which naturally often ended in nothing being done. Such was Professor Byers's gloomy conclusion.

THE recent sitting of the Swiss Medical Commission at Berne considered measures to prevent the intrusion of foreigners into medical practice in Switzerland.

THE Proceedings of the Medical Conference of Red Cross Societies, held at Cannes in April, 1919, have now been issued by the League of Red Cross Societies at Geneva in a volume containing portraits of the delegates.

THE LATE DR. R. J. BANNING.—The death of Robert Joseph Banning has occurred at his residence, Helidon, Shoeburyness, Essex, on Feb. 10th, aged 87. Dr. Banning saw the first excursion train leave Liverpool for London, and, during a visit to America, he met George Washington. He was born in Liverpool, where he received part of his medical education at the old medical school. He also studied at the Middlesex Hospital and qualified with the L.S.A. in 1854. As a civil surgeon he took part in the Crimean War and for his services was granted the medal. In 1857 he graduated M.D. at St. Andrews, and in 1858 became a Member of the Royal College of Surgeons of England. For a time he acted as honorary medical officer to the Gateshead Dispensary, subsequently practising at Shoeburyness. During the session 1894–95 he presided over the West London Medico-Chirurgical Society.

BRIGHTON AND HOVE DISPENSARY.—There should be no need to call attention to the excellent work that is being done by the Brighton, Hove, and Preston Dispensary, established over 100 years ago. Statistics of the past year's work give proof of the value of the institution to the townspeople. Yet the year 1919 closed with an overdraft of nearly £1500, and at the annual meeting of the governors it was declared that unless there were more annual subscribers the work of the institution would have to be curtailed by the closing down of some of the wards. A special effort is to be made to relieve the financial strain, and, realising the very useful work of women, the rules were altered so as to permit one-third of the governors to be women.

THE LATE DR. J. H. DAVIES.—John Hopkyn Davies, who died in London on Feb. 10th, was a well-known practitioner at Port Talbot, where he had lived for some 50 years. He was educated in his father's school at Newcastle Emlyn, and afterwards entered at the Middlesex Hospital, qualifying M.R.C.S. Eng. and L.S.A. in 1872. In 1889 he obtained the degree of M.D. Durh. Formerly medical officer to the Aberavon Urban District Council, Dr. Davies was at the time of his death in charge of the health of the Margam district, assistant health officer for Port Talbot, and superintendent of the Margam Sanatorium. He was on the commission of peace for Glamorgan.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-UPON-TYNE: ANNUAL REPORT.—The annual report of the Council was presented to the Court of Governors at their meeting on Feb. 11th. The report begins with an expression of regret for the death of Professor Frederick Page, who was appointed lecturer on medical jurisprudence in 1875 and filled the office of registrar for about 30 years. With regard to the present position of the medical school the report states:—

> The number of students at present in attendance is 389 (70 women and 319 men), and is the largest in the history of the College, being an increase of 150 over the year 1918, and 220 over that of 1917. This is mainly accounted for by the entrance of men who have been discharged from H.M. Forces since the signing of the peace. Preference of admission to the College was given to these men, about 120 of whom are in receipt of grants towards their maintenance and their tuition fees from the Board of Education. After admitting these ex-Service students it was found impossible, owing to want of accommodation, to receive a good many of the other students who applied.
>
> Although the entry of students will, no doubt, fall somewhat next winter the Council is of opinion that the present great demand for qualified medical men and women will not be met for a considerable number of years. In view of this, reference must again be made to the immediate need of increasing the accommodation and the facilities for teaching. During the past year the teaching staff has been strengthened by the appointment of additional assistants in the departments of anatomy, physiology, pathology, and bacteriology, but the endowment of a chair of medical chemistry (bio-chemistry) and a great increase in the laboratory and other accommodation of the College are crying needs.

A committee of the Council has reported that it is impossible to extend the College on its present limited site sufficiently to meet the requirements of modern medical education, and recommends the erection of a new and greatly enlarged College in the vicinity of the Royal Victoria Infirmary. It is estimated that a sum of about £250,000 will be required to erect and endow the new building. Residential hostels for male and female students are also needed, together with proper housing for the Students' Union Society. To provide these a further sum of about £30,000 is necessary. This College is the only school of medicine between Edinburgh and Leeds, and a good proportion of the medical practitioners of the North of England have been educated in it.

COMPLIMENTARY DINNER TO LORD DAWSON.

ON Wednesday evening, Feb. 25th, a dinner was given by the Federation of Medical and Allied Societies to Lord Dawson of Penn, the occasion being to congratulate him upon his elevation to the peerage. The dinner took place at the Café Royal, Sir Malcolm Morris, the chairman of the Federation, presiding, when a representative body of guests assembled, among those present being Dr. Addison (the Minister of Health), Lord Astor, Sir Robert Morant, Dr. Arthur Latham, Dr. Dawson Williams, Mr. E. B. Turner, Dr. G. E. Haslip, Lord Charnwood, Sir Ronald Ross, Sir W. Arbuthnot Lane, Dr. J. F. Gordon Dill, Dr. E. H. Stancomb, Mr. C. J. Bond, Sir John MacAlister, Dr. W. Elliot, M.P., Dr. Jane Walker, Miss L. Aldrich-Blake, Dr. R. H. Cole, Sir David Ferrier, and Dr. Squire Sprigge.

The Chairman, proposing the health of Lord Dawson, started by pointing out that the new peer might be seduced into giving gratuitous consultations in the Upper House, or be compelled by emergency to attend noblemen suffering from political shock, even from a precipitous fall from the Woolsack. Concluding in a more serious vein, he urged that the presence of a practising physician in the House of Lords was an earnest that in the future doctors would engage more closely in State affairs.

Lord Dawson, in reply, acknowledged frankly the pleasure it gave him to receive appreciation from a representative body of his own colleagues, and repeated Sir Malcolm Morris's message that in the new era medical men would take a greater share in State responsibilities.

Dr. Addison, protesting that he had definitely refused to make a speech, laid stress upon the important position which Lord Dawson occupied as Chairman of the Medical Consultative Committee under the Ministry of Health, and said that in a short time the first report from that body would be published, when its recommendations would have to be read seriously, though it did not follow that it would be possible to adopt them all.

Mr. Bond made an eloquent exposition of what the relations between the public and the medical profession should be in wishing prosperity to the Federation, to which Dr. Howard Mummery replied by stating very clearly the hopes and aims of that body. Mr. E. B. Turner proposed the health of the Chairman, who briefly replied.

The Services.

ARMY MEDICAL SERVICE.

Major-Gen. J. B. Wilson and Col. D. D. Shanahan are placed on half pay.

Temp. Col. A. S. Woodwark relinquishes his commission and retains the rank of Colonel.

Col. T. H. M. Clarke retires on retired pay.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. J. G. McNaught retires on retired pay.

Lieut.-Col. C. S. Smith is placed on the half-pay list on account of ill-health.

Major G. H. Stevenson to be acting Lieutenant-Colonel.

The undermentioned relinquish the acting rank of Major: Capt. and Bt.-Major W. E. Marshall; Capts. G. G. Collet and G. A. Bridge; Temp. Capts. P. P. J. Stewart and H. M. Anderson.

Major and Bt. Lieut.-Col. W. Benson relinquishes the acting rank of Lieutenant-Colonel.

Capt. W. S. Martin, from unattached list, T.F., to be Temporary Lieutenant.

Temp. Capt. (acting Major) R. G. Oram (Lieutenant, 9th Lond. R., T.F.) relinquishes his temporary commission.

Capt. P. C. Field is restored to the establishment.

Temp. Capt. H. A. Tillman to be acting Major whilst specially employed.

Officers relinquishing their commissions:—Temp. Hon. Lieut.-Col. J. H. Nicholl (retains the honorary rank of Lieutenant-Colonel). Temporary Majors retaining the rank of Major: W. P. Yetts, J. R. Lee, E. B. C. White. Temp. Hon. Major A. M. Westwater (retains the honorary rank of Major). Temp. Capt. (acting Lieut.-Col.) F. R. Fraser (granted the rank of Major). Temp. Capt. (acting Major) J. W. Innes (granted the rank of Major). Temporary Captains retaining the rank of Captain: J. B. Donaldson, R. H. Liscombe, S. F. McDonald, S. S. Rosebery, G. M. Jones, T. W. Kelly, E. C. Black, A. A. Henderson, C. V. Walker, W. P. Cooney, C. E. Meryon, A. C. B. McMurtrie, J. G. Jones, J. F. Bridge, H. M. Leathes, H. G. Steel, F. J. Fahy, W. R. Reynell, F. M. Bishop.

SPECIAL RESERVE OF OFFICERS.

Capt. J. R. Caldwell resigns his commission.

TERRITORIAL FORCE.

Capt. (acting Lieut.-Col.) J. Tait relinquishes the acting rank of Lieut.-Colonel on ceasing to be specially employed.

Capt. (temp. Major) A. E. Barnes relinquishes the temporary rank of Major.

Major H. H. B. Cunningham to be acting Lieutenant-Colonel whilst specially employed.

Capts. (acting Majors) J. G. F. Hosken and F. Arvor relinquish the acting rank of Major on ceasing to be specially employed.

Capt. J. M. Kirkness is restored to the establishment.

2nd London General Hospital: Capt. H. F. Lancaster is restored to the establishment.

1st Southern General Hospital: Major (Bt. Lieut.-Col.) (acting Lieut.-Col.) J. E. H. Sawyer relinquishes the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

3rd Northern General Hospital: Capt. A. E. Barnes to be temporary Major whilst specially employed.

TERRITORIAL FORCE RESERVE.

Capt. D. W. C. Jones, from General List, to be Colonel.

ROYAL AIR FORCE.

Medical Branch.—Flying Officer G. McK. Thomas to be Flight Lieutenant.

The undermentioned are transferred to the unemployed list: Capts. J. Gardner, G. Meadows, V. Magee; Lieuts. T. Acton, T. E. Roberts.

Dental Branch.—The undermentioned are transferred to the unemployed list: Capts. J. Smith, S. C. Turner.

INDIA AND THE INDIAN MEDICAL SERVICE.

THE Viceroy has selected Lieut.-Col. D. M. Davidson, Civil Surgeon, Lahore, to hold charge of the office of Inspector-General of Civil Hospitals, Punjab, in place of Col. R. C. MacWatt. Major C. E. Palmer, on return from military duty, has assumed charge as Superintendent, Central Prison, at Naini (Allahabad). Captain T. Fleming, R.A.M.C., acts as Civil Surgeon, Port Blair. The Chancellor of the Calcutta University has nominated Dr. Hassan Suhrawardy to be Ordinary Fellow of the Calcutta University. The following officers have reverted to civil employ: Lieut.-Col. G. McIver Smith (Punjab), Lieut.-Col. G. H. Stewart (Burma), Lieut.-Col. E. R. Parry (Bengal), Lieut.-Col. N. R. J. Ramier (Central Provinces). Major F. A. Barker has been appointed Senior Medical Officer in the Andamans and Major Cruikshank has been granted eight months' combined leave. Captain H. K. Downtree has been appointed Additional Assistant Director-General.

THE "ARM BADGE" OF THE R.A.M.C.

With respect to the arm badge of the N.C.O.'s and men of the R.A.M.C., Sir George Evatt writes from the Junior United Service Club making certain recommendations. The badge is worn, he points out, in peace on the sleeve of the tunic as a yellow and white ring with the Red Cross in centre. "It is small, not very distinctive, but is replaced in war by the definite broad white armlet with Red Cross in the centre. I propose to abolish the small yellow and white ring, and replace it *in peace* by the collar badge worn by the R.A.M.C. officers, and in war to give to both officers and men the very definite and unmistakable brassard of the Geneva Convention—viz., the Red Cross on the white brassard." The innovation is calculated, in Sir George Evatt's mind, to unite still more closely the officers, N.C.O.'s, and men of the R.A.M.C., who need the very closest union possible to achieve success in their important duties.

DEATHS IN THE SERVICES.

Surg.-Gen. James Albert Clery, C.B., A.M.S. (retired), died at his residence at Blackheath on Feb. 10th, in his seventy-fifth year. He entered the service in 1871 and during his 35 years in the army he saw a good deal of active service. In the Sudan Expedition of 1884–5, he obtained the medal with clasp and the bronze star, and in the Nile Expedition in 1898 he earned a mention in despatches and received two medals. In the South African War he was principal medical officer on the lines of communication, and was at the relief of Ladysmith. He was twice mentioned in despatches and was subsequently awarded the C.B., the Queen's medal with six clasps, and the King's medal with two clasps.

FOREIGN DECORATIONS.

Chinese.

Order of the Wen-Hu.—4th Class: Temp. Maj. (acting Lt.-Col.) W. H. G. Aspland, R.A.M.C.; Temp. Maj. S. M. Cox, R.A.M.C.; Temp. Maj. T. N. Frood, R.A.M.C.; Temp. Maj. (acting Lt.-Col.) G. D. Gray, O.B.E., R.A.M.C. *5th Class:* Temp. Capt. P. C. Leslie, R.A.M.C.; Temp. Capt. H. D. Matthews, R.A.M.C.; Temp. Capt. E. J. Peill, R.A.M.C.; Temp. Capt. J. W. Pell, R.A.M.C.; Temp. Capt. W. R. Reeds, R.A.M.C.

Panama Republic.

Medal of "La Solidaridad,"—3rd Class: Capt. (acting Maj.) W. K. Campbell, D.S.O., M.C., R.A.M.C.; Capt. and Bt. Maj. (acting Maj.) W. L. Webster, R.A.M.C.; Capt. (acting Maj.) J. M. Weddell, R.A.M.C.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 18TH.

Death-rate in British India.

Mr. LUNN asked the Secretary for India what was the death-rate per 1000 in British India from the years 1913 to 1919 inclusive.—Mr. FISHER (Minister of Education) replied: The death-rate per 1000 for the years 1913 to 1918 was as follows: 1913, 28·72; 1914, 30·00; 1915, 29·94; 1916, 29·10; 1917, 32·72; 1918, 62·42. Figures for 1919 are not available. The exceptionally high mortality in 1918 was due to a severe epidemic of influenza.

Municipal Maternity Homes.

Mr. CLOUGH asked the Minister of Health if he would state what action was being taken by his department to promote the establishment of maternity homes by municipal authorities.—Dr. ADDISON replied: The Local Government Board and the Ministry of Health have for some time pressed upon local authorities both in general circulars and in individual letters the importance of the provision and maintenance of maternity homes, and have obtained Treasury sanction for a grant of half the approved expenditure on these purposes. A memorandum has just been issued and will be placed on sale giving guidance as to suitable plans and equipment and so forth. During the last year or so about 25 such homes were established by municipal authorities and about 20 by voluntary bodies, who as a rule received financial assistance from local authorities. Many similar homes have been planned and are likely to be established in the near future.

Queen Alexandra's Nurses and Wound Gratuity.

Lord HENRY CAVENDISH-BENTINCK asked the Secretary for War if he would explain why a wound gratuity and wound pension was refused to Miss Eileen King, a member of Queen Alexandra's Nursing Service, who was severely wounded by hostile bombs while on military duty in France and passed permanently unfit for further military service.—Sir A. WILLIAMSON (Financial Secretary to the War Office) replied: Members of the Queen Alexandra's Imperial Military Nursing Service are not eligible for wound gratuities or wound pensions. The question of the rate of disability retired pay for which Miss King may be eligible is a matter for the Ministry of Pensions, and as I have already informed the noble Member, her case has been referred to that department.

Allegations against Army Medical Hospitals.

Major STEEL asked the Secretary for War whether his attention had been called to complaints alleged to have been made by patients in army mental hospitals regarding their treatment in such hospitals; whether such complaints had been investigated; if so, with what result; whether and, if so, in what respects the system of treatment in army mental hospitals had differed from the system of treatment generally adopted in mental hospitals under public control; whether he was satisfied with the results yielded by the present system of treatment; and whether he was prepared to order an inquiry into the allegations made directly against the officials of the army mental hospitals and indirectly against the Army Medical Department.—Mr. CHURCHILL replied: My attention has been called to the alleged complaints. Strict orders were issued by the Director-General, Army Medical Service, that every complaint, however made or of whatever nature, should be immediately inquired into. These orders, I believe, have been strictly observed, and such action as inquiry justified has invariably been taken. In no case has it been found that there was ground for serious complaint, and the suggestions of careless treatment and of deliberate ill-treatment in these hospitals are unjustified. The utmost care has been taken in the treatment of soldiers suffering from early mental disorders, and the system of treatment followed, which was adopted after consultation with the most expert authorities on the subject, has been acknowledged by those best qualified to judge to be in some respects an improvement on the system generally adopted in civil mental hospitals. The results have been highly satisfactory, as is evidenced by the higher recovery-rate and the lower death-rate as compared with civil institutions of similar type. I am satisfied that the general allegations made against the officials of the army mental hospitals and the Army Medical Service are entirely unjustified, and I see no occasion for ordering an inquiry of the nature suggested.

Vaccination.

Mr. CHARLES EDWARDS asked the Minister of Health whether he was aware that more than half the children born at the present time were withheld from vaccination; whether under the present Vaccination Acts the proportion of unvaccinated children of each year's birth was steadily increasing; whether nearly 40 per cent. of the births each year were exempted from vaccination by the statutory declaration of their parents of objection to the operation; and in what way would the health of the community be involved by the repeal of the compulsory clauses of the Vaccination Acts, seeing that under present conditions such a large number of children remained unvaccinated, while small-pox was less prevalent than in the years when a far larger proportion of children were vaccinated.—Dr. ADDISON replied: The facts are approximately as stated in the first part of the question. I am, however, of opinion that the repeal of the compulsory clauses of the Vaccination Acts would result in a still larger proportion of children remaining unvaccinated, and thus the whole community would be less protected. Small-pox is prevalent at the present time in various parts of Europe, Canada, and America, and in view of the risks of the introduction of the disease into this country I am not prepared to take any action which would tend to increase the number of persons in this country who are unprotected by vaccination.

National Health Insurance Accounts.

Captain COOTE asked the Minister of Health whether he could give figures showing the receipts and expenditure for the past year under the National Health Insurance Act; whether he was aware of the inadequacy, felt in many instances, of the maximum benefit of 5s. per week; and whether there was any possibility of an increase of this amount being granted, with or without an increase in the rates of contribution.—Dr. ADDISON replied: As regards the first part of the question the only figures at present available are those of receipts and payments of the National Health Insurance funds, a summary of which I am circulating. As regards the second and third parts of the question the revision of health insurance contributions and benefits has been under consideration for some time, and I hope to be in a position to introduce a Bill to amend the existing provisions at an early date. The summary of accounts is as follows:—

Statement of Receipts and Payments of the National Health Insurance Funds (England and Wales) in the Year 1919.

RECEIPTS.		£
Balance at Dec. 31st, 1918		801,880
Sale of stamps		14,386,898
Contributions paid in cash		1,730,275
Exchequer grants		6,609,226
Interest on investments in securities selected by societies held on behalf of societies		247,213
Sums withdrawn from temporary investment		415,000
		£24,190,492
PAYMENTS.		
Issues to meet cost of benefits and expenses of administration:—	£	
Approved Societies	8,695,898	
Insurance Committees, &c.	7,068,017	
Deposit contributors and Navy and Army Insurance Fund, &c.	184,009	
		15,947,924
Issues to Societies for Investment		7,810,989
National Debt Commissioners: Investments on behalf of Approved Societies (Officers) Guarantee Funds		2,800
Miscellaneous		1,329
Balance at 31st December, 1919		427,450
		£24,190,492

THURSDAY, FEB. 19TH.

War Office and Metropolitan Asylums.

Lieutenant-Colonel JAMES asked the Secretary for War if he would state the number of beds belonging to the Metropolitan Asylums Board still held by the War Office.—Mr. CHURCHILL replied: Only three Metropolitan Asylums Board institutions are not yet handed back to that Board—the Tooting Grove, the Lower Southern Hospital at Dartford, and the Orchard Hospital at Dartford. These three hospitals are empty or in process of being evacuated and will be finally handed over on the 29th of this month. It is understood that for the purposes of accommodation for civilian infectious cases the number of beds in these three institutions is reckoned at 1947.

Dental Legislation.

Mr. RAFFAN asked the Minister of Health whether it was proposed to introduce legislation during the present session of Parliament for the purpose of carrying out the recommendations of the Departmental Committee on the Dentists Act, 1878.—Dr. ADDISON: It is hoped to introduce legislation during this session, but I am not yet in a position to make a definite statement.

Veterinary Surgeons Act, 1881, Amendment.

Sir WATSON CHEYNE presented a Bill "to amend the Acts relating to the practice of veterinary surgery and medicine." The Bill was read a first time.

MONDAY, FEB. 23RD.

Precautionary Measures in Influenza.

Dr. NATHAN RAW asked the Minister of Health whether he could make any statement as to the incidence of influenza in this country, and what preparations had been made by the Minister of Health for dealing with an epidemic should it occur.—Dr. ADDISON replied: There has been a slight increase in the number of deaths from influenza during recent weeks and a few significant outbreaks in schools and other institutions, but otherwise there is no evidence at present of unusual prevalence of the disease in this country comparable to the definite new waves of influenza which are occurring in American cities and on the Continent. The Ministry keep a constant watch on the occurrence of influenza at home and abroad, and have put themselves in a position to observe closely the progress of any epidemic wherever it may occur. Information is derived from returns as to epidemics obtained from Consular agents and from other official sources all over the world. As regards the prevalence of the disease at home information is obtained from the weekly returns of influenza mortality in the 96 great towns issued by the Registrar-General and from returns of cases of acute influenzal-pneumonia, the notification of which is not obligatory on all medical practitioners in England and Wales. Returns of cases of influenza are also furnished voluntarily every week by a number of schools, institutions, and representative industrial firms throughout the country. All data on the subject, statistical as well as scientific, come before an Influenza Committee, which is a Medical Standing Committee of the Ministry of Health holding frequent meetings and on which sit medical representatives of various Government Departments. A vaccine against influenza has been prepared by the Ministry and is now being issued on demand to medical officers of health for distribution free of charge among medical practitioners within their districts. Careful consideration has been given to all practicable means of protecting the country from the introduction of influenza through the ports. The knowledge and experience accumulated during recent epidemics have been collected and issued to local authorities at various times in the last 12 months. A Memorandum has been issued to local authorities explaining the measures (both administrative and personal) which with our present knowledge are deemed best calculated to prevent the spread of influenza and to lessen mortality from the disease. A popular leaflet has also been issued and widely circulated through local authorities setting out the best measures of guarding against infection, together with advice to patients as to the best known means of securing a speedy return of convalescence and the avoidance of those complications which constitute the special danger of influenza. Meanwhile, much active investigation continues by the medical officers of the Ministry into the causes of epidemics of influenza. Special inquiry is being made by them in selected districts into such questions as immunity, the effects of overcrowding, incidence according to age, and so on. In certain of these areas arrangements have been made, in consultation with the Medical Research Committee, for the coöperation of medical officers of the Ministry, medical officers of health, and bacteriologists in the investigation of the origin, the spread, and best means of combating the disease.

Professional Training for Ex-Service Men.

Replying to Mr. ALFRED DAVIES, Sir R. HORNE (Minister of Labour) stated that he understood from the Minister of Education that he had sanctioned grants to some 2408 men training in the medical and dental professions.

Part-time and Whole-time Medical Remuneration.

Major HENDERSON asked the Parliamentary Secretary to the Pensions Ministry if he would state the remuneration of part-time and whole-time medical officers employed in the London area.—Sir J. CRAIG replied: Part-time medical officers are paid by a fee per session of two and a half hours. The fee varies from 1¼ guineas to 2 guineas, according to the class of work required. Whole-time medical officers in the London area are paid annual salaries ranging from £750 to £1200.

Schools for Defective and Epileptic Children.

Major HILLS asked the President of the Board of Education if he would state when the obligation to establish special schools, other than boarding schools, for physically defective and epileptic children became operative.—Mr. FISHER replied: Section 20 of the Education Act, 1918, comes into operation on April 1st next.

Treatment of Service Mental Cases.

The House went into Committee of Supply on Army Estimates for 1920-21, Mr. WHITLEY in the chair.

On a vote on account of £75,000,000 for Army Services,

Mr. SPOOR called attention to the War Office treatment of mental cases. Nothing that modern science or human goodwill could do, he said, was too much to be done for these men. Allegations had been made in the press of a most serious character. If 15 per cent. of truth was contained in those allegations there was abundant justification for an immediate and impartial inquiry. The honourable Member quoted from a paragraph which he said had appeared in the *Daily Herald* to the effect that it was estimated that between 20.000 and 30,000 shell-shock patients had been treated in the military hospitals. Many of the brave men sent back from France speechless or witless for the time being through shock were given the treatment of prisoners in gaol.

Sir A. WILLIAMSON, replying for the War Office, said that in 1915 the President of the Royal College of Physicians, at the invitation of the Army Council, arranged for a committee of members of the College to visit the various military hospitals in which nerve shock and mental cases were being treated and to submit a report on the adequacy or otherwise of the arrangements made for the care and treatment of the patients. There was a report which was satisfactory, and further supervision had been made of these hospitals and asylums and patients. Hospitals were frequently visited and it was the unvarying rule that any complaint was immediately investigated. Some cases had been investigated and there was found to be no foundation for the statements which had been made. Several allegations had been made, however, against the Lord Derby War Hospital, and the visiting committee and the hospital immediately pressed for an independent inquiry, and the War Office authorities were fully prepared to offer every facility for the fullest inquiry on a prima facie case for inquiry being shown.

Brigadier-General PAGE CROFT said that he thought that Mr. Spoor should not make statements such as he had made unless he had proved the facts, because it was an unpardonable calumny against the conduct of the authorities of this country. Although he had had a great deal to do with many of these mental cases he had never heard charges of that description before.

The vote was agreed to.

Communications, Letters, &c., to the Editor have been received from—

A.—Mr. G. G. Alderson, Kenilworth; Mr. A. S. Anderson, Northampton.

B.—Mr. G. P. Blizard, Lond.; Board of Trade, Lond.; Bread and Food Reform League, Lond., Sec. of; Miss W. F. Buckley, Lond.; Dr. W. B. Bell, Liverpool.

C.—Mr. F. R. Cave, Bath; Central Council for District Nursing in London, Hon. Sec. of; Chadwick Trust, Lond.; Dr. H. C. Cameron, Lond.; Dr. R. Creasy, Lond.

D.—Dr. T. B. Davies, Lond.

F.—Mr. J. E. Frazer, Lond.

Z.—Mr. A. M. Zamora, Lond.

YALE UNIVERSITY.—Two Seessel Fellowships, of the value of $1000 each, are offered for original research in biological studies at Yale University. These Fellowships are open to either men or women. In making the award, preference is given to graduates of universities who have already obtained their Doctorate, and who have demonstrated by previous work their fitness to carry on successfully original research of a high order in one of the three departments of biological studies: physiology (including physiological chemistry), zoology, and botany. Applications for these Fellowships must be made to the Dean of the Graduate School, Yale University, New Haven, Connecticut, before May 1st, and should be accompanied by (1) reprints of scientific publications by the applicant; (2) letters of recommendation; (3) a statement of the particular problem to be investigated.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, March 2nd.

SURGERY: SUBSECTION OF ORTHOPÆDICS (Hon. Secretaries—A. S. Blundell Bankart, R. C. Elmslie): at 5 P.M.

Cases and Specimens:

Mr. Laming Evans: (1) Osteosclerosis of the Femur; (2) Skiagram and Microscopic Section of Periosteal Sarcoma of the Femur.

Mr. W. T. Gordon Pugh: (1) Exostosis of the Radius; (2) Achondroplasia.

Mr. R. C. Elmslie: (1) Mid-Carpal Fracture-dislocation; (2) Cyst of the Tibia.

PATHOLOGY (Hon. Secretaries—J. A. Murray, Cecil Price-Jones): at 8.30 P.M.

Mr. A. H. Drew and Dr. J. A. Murray: Observations on the Staining and Constitution of Mitochondria.

Dr. E. H. Kettle: Demonstration of Experimental Aspergillosis in the Rabbit.

Dr. Da Fano: Summary of Recent Work on Disseminated Sclerosis.

Wednesday, March 3rd.

SURGERY (Hon. Secretaries—Cyril A. R. Nitch, Herbert J. Paterson): at 5.30 P.M.

Specimens will be on view from 4.30 P.M.

Discussion:

On "The Remote Results of the Surgical Treatment of Gastric and Duodenal Ulcers," with exhibition of specimens. To be opened by Mr. Herbert J. Paterson. The following Members have promised to take part in the discussion:—The President (Sir John Bland-Sutton), Sir D'Arcy Power, Mr. W. G. Spencer, Dr. Robert Hutchison, Mr. James Sherren, Dr. Chas. Bolton, Mr. G. Grey Turner, Mr. Garnett Wright, Mr. Cyril Nitch, Dr. A. F. Hurst, Mr. Chas. Ryall, Mr. Jocelyn Swan, Mr. H. W. Carson, Mr. Joseph Cunning, Sir Crisp English, Mr. R. P. Rowlands, Mr. A. J. Walton.

OPHTHALMOLOGY (Hon. Secretaries—Malcolm Hepburn, W. H. McMullen): at 8 P.M.

Cases and Specimens:

Mr. Leslie Paton: Cobalt Glass for Use in Estimating Refraction.

Mr. W. H. McMullen: Lacrymal Cyst.

Papers (8.30 P.M.):

Mr. Leslie Paton: Note on the Use of Cobalt Glass in Estimating Refraction.

Mr. Charles Goulden: Treatment of Prolapse of the Iris following Accident, with a Note on the Removal of Non-magnetic Foreign Bodies from the Anterior Chamber.

Thursday, March 4th.

BALNEOLOGY AND CLIMATOLOGY (Hon. Secretaries—J. Campbell McClure, C. F. Sonntag, F. G. Thomson): at 5.30 P.M.

Dr. W. Edgecomb: Visceral Fibrositis.

Discussion:

On Dr. Ferreyrolles's paper "Immunity and Mineral Water Treatment." (See Proceedings, vol. xii., No. 9, August, 1919.)

Exhibition by Dr. C. F. Sonntag of a Painting of Bagnigge Wells in 1790.

Members of the Section of Pathology are cordially invited to attend this meeting.

OBSTETRICS AND GYNÆCOLOGY (Hon. Secretaries—J. S. Fairbairn, Herbert Williamson): at 8 P.M.

Specimen:

Mr. V. Zachary Cope: Interstitial Ectopic Gestation.

Short Communications:

Dr. Gordon Luker: (1) Rupture of the Bladder associated with Three Months' Pregnancy; (2) Late Post-partum Hæmorrhage treated by Blood Transfusion and Panhysterectomy.

Paper:

Mr. Gordon Ley: Utero-placental Apoplexy (Accidental Hæmorrhage). An Analysis of 50 Cases.

Friday, March 5th.

LARYNGOLOGY (Hon. Secretaries—Irwin Moore, Charles W. Hope): at 4.45 P.M.

Cases and Specimens (4 P.M.) will be shown by—

Dr. Dundas Grant, Mr. Douglas Harmer, Dr. William Hill, Dr. Kelson, Sir William Milligan, Mr. W. M. Mollison, Dr. Irwin Moore, Mr. Rose, Dr. Scripture, and Dr. Andrew Wylie.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 1st.—9 P.M., Lettsomian Lecture: Dr. H R. Spencer: Tumours Complicating Pregnancy, Labour, and the Puerperium. (Lecture III.)

RONTGEN SOCIETY, in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole-street, W.

TUESDAY, March 2nd.—8 P.M., General Meeting. Silvanus Thompson Memorial Lecture:—Prof. W. H. Bragg: Analysis by X Rays.

ASSURANCE MEDICAL SOCIETY, at the Medical Society of London, 11, Chandos-street, W.

WEDNESDAY, March 3rd.—5 P.M., Council Meeting. 5.30 P.M., Presidential Address:—Dr. T. D. Lister.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East.

TUESDAY, March 2nd, AND THURSDAY.—5 P.M., Milroy Lectures:—Dr. A. Castellani, C.M.G.: The Higher Fungi in Relation to Human Pathology. (Lectures II. and III.)

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, in the Hall of the College, 9, Queen-street, Edinburgh.

Monday, March 1st, Wednesday and Friday.—5 p.m., Morison Lectures:—Dr. R. G. Rows: Mental Illnesses.

UNIVERSITY OF LONDON.

Advanced Lectures in Physiology to Students of the University and others interested in the subject.

A Course of Eight Lectures on Physiologically Balanced Solutions will be given by Dr. W. L. Symes in the Physiological Laboratory of the University, South Kensington, S.W.:—

Tuesday, March 2nd.—5 p.m., Lecture VI.

A Course of Eight Lectures on the Reaction of the Blood and Acidosis will be given by Dr. J. W. Trevan, at St. Bartholomew's Hospital, West Smithfield, E.C.:—

Wednesday, March 3rd.—4.30 p.m., Lecture VI.

LONDON HOSPITAL MEDICAL COLLEGE (University of London), Mile End, E.

A Course of Instruction on the Diseases of Children, open to Post-Graduates and to Students of the Hospital. (The lectures will be illustrated by lantern slides.)

Monday, March 1st.—9.15 a.m., Lecture VIII.:—Dr. Thompson: Organic and Functional Nervous Diseases, Meningitis and Mental Deficiency. (At the Anatomical Theatre.)

Wednesday.—10 a.m., Clinical Demonstration:—Dr. Miller. (At the Children's Out-patient Department.)

Saturday.—10.15 a.m., Lecture IX., Dr. Hutchison: General Diseases. (At the Anatomical Theatre.)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (University of London).

A Course of Lectures on Syphilis is being given by various members of the staff of King's College Hospital during the present year.

Friday, March 5th.—9.15 p.m., Prof. Sir StClair Thomson: Syphilis of the Throat, Larynx, &c.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, W.

Monday, March 1st.—11 a.m., Out-patients: Dr. Goodall. 2 p.m., In-patients: Dr. Moon.

Tuesday.—2 p.m., Out-patients: Dr. R. Wells. 3 p.m., In-patients: Dr. Gibbes.

Wednesday.—2 p.m., Out-patients: Dr. Moon. 5.30 p.m., Lecture:—Dr. Moon: Syphilis and the Circulatory System.

Thursday.—10 a.m., In-patients: Dr. Hamill: 2 p.m., Out-patients: Dr. Price.

Friday.—2 p.m., Out-patients: Dr. Gibbes. 2.30 p.m., In-patients: Dr. Wells.

Saturday.—10.30 a.m., In-patients: Dr. Hamill.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.

Special Course of Lectures and Demonstrations on Tuberculosis for Medical Men and Women qualifying to become Tuberculosis Officers, General Practitioners, and others. Bacteriological Demonstrations will be given in the Laboratories of the Institute, and visits arranged to Sanatoriums, Tuberculosis Dispensaries, &c.

Thursday, March 4th.—5 p.m., Lecture VIII.:—Dr. T. G. Maitland: Hospital Treatment of Pulmonary Tuberculosis.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Tuesday, March 2nd.—2 p.m., Demonstration (I.):—Dr. A. J. Whiting: The Early Diagnosis of Pulmonary Tuberculosis. 4.30 p.m., Lecture:—Dr. J. H. Evans: Septic Conditions of the Gall Bladder and Bile Passages.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, W.C. 1.

MEDICAL SCHOOL.

Monday, March 1st.—2–3.30 p.m., Out-patient Clinic: Dr. Collier. 3.30 p.m., Ward Cases: Dr. Aldren Turner.

Tuesday, March 2nd.—2–3.30 p.m., Out-patient Clinic: Dr. Grainger Stewart. 3.30 p.m., Dr. Risien Russell.

Wednesday, March 3rd.—2 p.m., Mr. Sargent: Injuries of Peripheral Nerves and their Surgical Treatment. (I.) 3.30 p.m., Dr. James Taylor: Subacute Combined Degeneration of Spinal Cord.

Thursday, March 4th.—2–3.30 p.m., Out-patient Clinic: Dr. Farquhar Buzzard. 3.30 p.m., Dr. Hinds Howell: Syphilis of the Nervous System. I.

Friday, March 5th.—2–3.30 p.m., Out-patient Clinic: Dr. Gordon Holmes. 3.30 p.m., Ward Cases: Dr. Collier.

Saturday, March 6th.—9 a.m., Surgical Operations.

Fee for Post-Graduate Course £7 7*s*. C. M. Hinds Howell, Dean.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Saturday, Feb. 28th.—10 a.m, Mr. Banks Davis: Operations of the Throat, Nose and Ear.

Monday, March 1st.—5 p.m., Dr. Robinson: Gynæcology.

Tuesday.—5 p.m., Mr. T. Gray: Congenital Dislocation of the Hip.

Wednesday.—2 p.m., Mr. D. Armour: Special Surgical Cases.

Thursday.—5 p.m., Lecture:—Mr. Baldwin: Practical Surgery.

Friday.—5 p.m., Special Lecture:—Dr. D. Hood: Some of the Clinical Aspects of Aortic Disease.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton, S.W.

Wednesday, March 3rd.—4.30 p.m., Dr. Batty Shaw: Body Weight in Adult Consumptives.

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE POST-GRADUATE DEMONSTRATIONS, at the Sheffield Royal Hospital.

Monday, March 1st.—3.30 p.m., Dr. Nutt: X Ray Examination of Intestinal Tract.

Tuesday.—4 p.m., Dr. Hay: Hemianopia: Cerebral Localisation.

Wednesday.—3.30 p.m., Dr. Wilkinson: Minor Aural Cases and their Management.

Thursday.—3.30 p.m., Dr. Skinner: Acne Vulgaris: Ringworm, &c.

Friday.—4 p.m., Dr. Hay: Diseases of Retina and Choroid.

UNIVERSITY OF BIRMINGHAM—FACULTY OF MEDICINE, in the Anatomical Theatre, Edmund-street, Birmingham.

Post-Graduate Course of Lectures on Venereal Disease:—

Wednesday, March 3rd.—4.15 p.m., Dr. E. Assinder: Pathological Aspect of Venereal Disease.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

Tuesday, March 2nd.—4.30 p.m., Lecture:—Prof. H. R. Dean: The Wassermann Reaction.

SALFORD ROYAL HOSPITAL and ANCOATS HOSPITAL POST-GRADUATE DEMONSTRATIONS, at the two Hospitals alternately.

Thursday, March 4th.—4.30 p.m., Lecture:—Dr. Ashby: Treatment of Heart Disease in Children. (At Salford Royal Hospital.)

BRIGHTON DIVISION OF THE BRITISH MEDICAL ASSOCIATION, at the Sussex County Hospital.

Thursday, March 4th.—4 p.m., Clinical Demonstration.

Appointments

Chronnell, J., M.R.C.S., L.R.C.P., has been re-appointed Whole-time Officer to the Urban District of Hindley.

Grant, J. C. B., M.B., Ch.B. Glasg., has been appointed to the Chair of Anatomy in the University of Manitoba.

Pearson, W. J., D.M. Oxon., M.R.C.P. Lond., Physician to Out-patients, Hospital for Sick Children, Great Ormond-street.

Saint, C. F. M., C.B.E., M.S., F.R.C.S., Professor of Surgery in the University of Cape Town.

Stibbe, E. P., M.R.C.S., L.R.C.P. Lond., to the Chair of Anatomy in the School of Mines and Technology, Johannesburg.

Warburton, G. B., Ch.M., F.R.C.S. Eng., Assistant Surgeon, Manchester Children's Hospital.

Williamson, A. J., M.D., D.P.H., Assistant Medical Officer of Health for Essex and Medical Officer of Health for the Lexden and Winstree Rural District.

Certifying Surgeons under the Factory and Workshop Acts: Browne, H. J. M., M.D. Edin. (Hoylake); Smith, J. G. (Buckie); Lister, T. E., M.B., Ch.B. Leeds (Wakefield); Cutler, F. J., M.R.C.S., L.R.C.P. Lond. (Hastings); Binns, C. C. H., M.B., B.C. Cantab. (Leicester, East); Leigh, H. V., M.B., B.S. Durh. (Nelson).

School Medical Inspectors to the Essex Education Committee: Rankine, Mary D., M.B. Edin., and Weir, Mary M., M.B. Glasg.

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne District Infirmary.—Asst. H.S. £200. Second Asst. H.S. £150.

Birkenhead Borough Hospital.—Sen. and Jun. H.S.'s. £200 and £170.

Birmingham Dudley-road Hospital.—Sen. Asst. M.O. £375. Also Jun. M.O. £275.

Bridgend, Glamorgan County Asylum.—Jun. Asst. M.O. £350.

Bristol General Hospital.—Pathologist and Curator of the Museum. £500. Also Two H.P.'s, H.S., Obstet.O., and H.S. All £175.

Bristol, Ham Green Isolation Hospital and Sanatorium, Pill, near Bristol.—Asst. Res. M.O. £300.

Cambridge, Addenbrooke's Hospital.—Hon. Asst. P.

Cambridgeshire Mental Hospital, Fulbourn, near Cambridge.—Asst. M.O. £400.

Chartham, near Canterbury, Kent County Mental Hospital.—Jun. Asst. Third M.O. £300.

Chichester, West Sussex County Mental Hospital.—Second Asst. M.O. £350.

City Dispensary, 29 and 30, College-street, Dowgate Hill, E.C.—P.

Croydon Borough Hospital for Infectious Diseases.—Res. M.O. £500. Asst. Res. M.O. £350.

Croydon County Borough Mental Hospital, Upper Warlingham, Surrey.—Second Asst. M.O. £500.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £200. Asst. H.S. and Cas. O. £200.

Devonport, Royal Albert Hospital.—H.S. £200.

Doncaster Borough.—Asst. M.O. and Sch. M.O. £500.

Dorchester, Dorset County Council Education Committee.—School Dentists. £400.

East Suffolk County Education Committee.—Dentist. £400.

Essex County Council and Clacton Urban District Council.—Asst. County M.O.H. and M.O.H. £600.

Essex County Council.—Asst. County and Sch. M.O. and Mental Expert. £750.

Gateshead Dispensary.—Asst. M.O.

Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—H.P and Asst. H.S. £175 and £150 each.

Great Northern Central Hospital, Holloway, London, N.—Path. Asst. 300 gs. Also S.

Hampstead Infirmary.—Res. Med. Supt. £700.

Huddersfield, Bradley Wood Sanatorium for Pulmonary and Surgical Tuberculosis.—Res. M.O. £500.

Johannesburg (University of South Africa), South African Medical School of Mines and Technology.—Prof. Vet. Anat. £800.

Lancashire County Council, School Medical and Child Welfare Department.—Two Asst. County M.O.'s. £800.

Lancaster County Asylum.—Asst. M.O. £300.

Leeds Education Committee.—Sen. Sch. Dent. O. £600. Asst. Sch. Dent. O. £450.

Leeds Public Dispensary.—Res. M.O. £200. Also Hon. Radiologist.

Leicester City Hospital and Sanatorium, Groby-road.—Two Res. M.O.'s. £400 and £300.

Liverpool, David Lewis Northern Hospital.—Two H.P.'s and Three H.S.'s. £150.

Liverpool, Royal Southern Hospital.—Hon. Ophthal. S. Also Hon. Asst. P. Also two H.P.'s and three H.S.'s £100.

Liverpool, West Derby Union, Mill-road Infirmary.—Asst. Res. M.O. £280.

London Lock Hospital, Harrow-road, W.—H.S. £300.
London Temperance Hospital, Hampstead-road, N.W.—Medical Registrar. 40 guineas.
Loughborough and District General Hospital and Dispensary.—Res. H.S. £200.
Maidenhead, Bray Court, Home for Neurasthenic Sailors and Soldiers.—Res. M.O. £500.
Maidstone, Kent County Ophthalmic Hospital.—Hon. Aural S.
Maidstone, West Kent General Hospital.—H.P. £200.
Manchester Children's Hospital, Pendlebury, near Manchester.—Res. M.O. £150. Also Asst. P. £50.
Manchester, St. Mary's Hospitals for Women and Children.—Asst. M.O. £75.
Manchester Royal Eye Hospital.—Hon. P. Also Jun. H.S. £120.
Middlesex Hospital.—Cas. Surg. O.
Miller General Hospital for South-East London, Greenwich, S.E.—M.O. Also H.P. and Registrar. £100.
Monmouthshire Education Committee.—Asst. M.O. £500. Also Sch. Dentist. £400.
Newark-on-Trent, Newark Hospital and Dispensary.—Res. H.S.
Newcastle-upon-Tyne, City Hospital for Infectious Diseases, Walker Gate.—Res. M. Asst. £350.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Anæsth. £120.
Newport Education Committee.—Dentist. £500.
Norwich City.—Asst. Sch. M.O. £500.
Norwich, Norfolk and Norwich Hospital.—H.S. £200.
Nottingham General Hospital.—Hon. M.O. for X Ray and Electro-Therapeutic Dept. Also H.P. £150.
Portsmouth Workhouse Infirmary, Workhouse and Children's Home.—First. Asst. M.O. £300.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S.
Queen Mary's Hospital for East End, Stratford, E.—H.P. and H.S.
Queensland, Institute Tropical Medicine, Townsville.—Physiologist and Biochemist. £700.
Reading, Royal Berkshire Hospital.—Pathologist. £600.
Rousay and Egilshay, Orkney.—Res. M.O. £300.
Royal Chest Hospital, City-road, E.C.—H.P. £120.
Royal Institute of Public Health, 37, Russell-square, London, W.C.—Sen. Demonstrator of Bacteriology.
St. Bartholomew's Hospital and College.—Demonstr. of Pathology.
St. Mary's Hospital for Women and Children, Plaistow, London, E.—Res. M.O. £200.
Salford Royal Hospital.—Res. S.O. £250. H.P. £200. H.S., Jun. H.S., and Cas. H.S., £150 each.
Scunthorpe and Frodingham Urban District Council.—M.O.H. and Venereal Diseases Officer. £600.
Seamen's Hospital Society, Dreadnought Hospital, Greenwich.—P. 50 gs. Three Anæsth.'s. 50 gs. H.S. £100.
Sheffield Children's Hospital.—H.S. £200.
Sheffield Royal Hospital.—Asst. Cas. O. £150.
Sheffield Royal Infirmary.—Radiologist. £100.
Southampton, Royal South Hants and Southampton Hospital.—Sen H.S. £250. H.P. £150.
Southport General Infirmary.—Jun. H.S. £175.
South Russia.—M.O. as Medical Adviser to Red Cross Unit. £700.
Stamford, Rutland, and General Infirmary.—H.S. £200.
Sunderland, Royal Infirmary, Children's Hospital.—Res. M.O. £200.
Taunton and Somerset Hospital.—Hon. P. and Hon. S.
Turks and Caicos Islands.—M.O. £400.
University College Hospital Medical School.—Radcliffe Crocker Travelling Scholarship in Dermatology. £280.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—P.'s.
Warwick County Lunatic Asylum.—Sec. Asst. M.O. £300.
Wigan County Borough Education Committee.—Sch. Dentist. £150.
Willesden Institution, Acton Lane.—Res. Asst. M.O. £300.
Winchester, Royal Hampshire County Hospital.—H.P. £250.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Toddington, Berkeley, Lochgilphead, Bruff, Clonakilty, Belturbet, Halstead, Stock, Stourport, and at Romford.

Births, Marriages, and Deaths.

BIRTHS.

BANBURY.—On 26th January, at 107, East Dulwich Grove, S.E., the wife of R. A. Banbury, M.R.C.S., L.R.C.P., of a daughter.

MALING.—On Feb. 13th, at Walthamstow, the wife of G. A. Maling, V.C., M.B., of a son.

THOMPSON.—On Feb. 19th, at Royal Hospital, Chelsea, the wife of Major R. J. C. Thompson, C.M.G., D.S.O., R.A.M.C., of a son.

WILLIAMSON.—On the 23rd February, at "Thurlstone," Kingston-road, Romford, to Dr. and Mrs. A. J. Williamson—a son.

MARRIAGES.

WESTBY—MCMULLEN.—On Feb. 16th, 1920, at St. Ann's Church, Dublin, by Rev. B. W. Keymer, C.F., R.A.F., assisted by the Rev. Canon Day, Vicar, John Thorp Westby, M.B., B.Ch. (T.C.D.), only son of the late Dr. A. J. Westby and Mrs. Westby, 32, Waterloo-road, Dublin, to Marjorie McMullen, L.R.C.P. & S.I., younger daughter of the late Robert B. McMullen and Mrs. McMullen, 2, Arranmore-road, Herbert Park, Dublin.

DEATHS.

ADCOCK.—On Feb. 20th, at Purbeck House, Weymouth, Brigade Surgeon John Adcock, Army Medical Service, aged 82 years.

FERGUSSON.—On Feb. 21st, at the Hydropathic Establishment, Great Malvern, John Campbell Fergusson, M.D., L.R.C.P. & S. Edin., L.R.F.P.S. Glasg., in his 85th year.

WHIPPLE.—On Feb. 20th, at Redcliffe-square, South Kensington, Lieutenant-Colonel John Henry Connell Whipple, M.D., A.M.S. (retd.), late Coldstream Guards, in his 79th year.

WORNUM.—On Feb. 18th, at Hillside, Farningham, Kent, George Porter Wornum, M.R.C.S., aged 62 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

THE INSANITY OF JOHN BUNYAN.[1]

BY THE REV. E. G. O'DONOGHUE.

CHAPLAIN OF BETHLEM ROYAL HOSPITAL.

SO far as I can ascertain, nobody has hitherto realised that Bunyan was insane, in the technical and medical sense of the word, for three or four years of his life—say between 1650 and 1653. His book, "Grace Abounding," contains particulars sufficient to fill up the certificate and case-book of the mental specialist. Premonitory symptoms of the latent disease manifested themselves from time to time, and in 1651 the "great storm came stealing" upon him, and "floods of blasphemies," unprovoked and unexpected, overwhelmed his mind. The "unpardonable sin" began to have a horrible fascination for him. He "desired to commit it," and soon came to believe that he had committed it. Sometimes he "felt the tempter pull his clothes"; sometimes the Devil seemed to "take the form of a bull, bush, or besom," inviting him to fall down and worship him. Then for a whole year one sentence iterated and reiterated itself on the anvil of his diseased brain, "Sell Christ!" "Sell Christ!" "Sell Christ!"

For two whole years at least, as I understand the narrative, the "masterless hounds of hell ran over his soul, roaring and bellowing." He had, at last, committed the unpardonable sin; he was now racked day and night with the anticipation of descending before another day had passed into eternal torment. Like other victims of religious melancholia, he added to his physical agitation and mental agony by ransacking the Scriptures to justify the appalling sentence of everlasting damnation pronounced against his soul!

Such was the fiery trial which made John Bunyan what he came to be. Out of it came the iron—dug in darkness, heated red hot in the furnace of his afflictions, tempered in the bath of his own tears—which went to the building up of his greatest work, the "Pilgrim's Progress."

The armour of Christian is dinted with the marks of his terrible conflict with Apollyon. But it was John Bunyan himself who could find no firm ground under his feet in the slough of religious despondency. It was he who had been in the iron cage when he thought that he had "sold Christ," and "committed the sin against the Holy Ghost." John Bunyan, and none but he, had been through the Valley of the Shadow of Death before he wrote about it; in it he had uttered the grievous blasphemies which the fiend seemed to have put into his mouth; on his pilgrimage through it "clouds of confusion" had sometimes settled on his head, sometimes "doleful voices" moaned in his ear, or he heard a "company of fiends rushing and yelling" around him.

Christian was not the only pilgrim who heard "Bedlam" shouted after him in Vanity Fair.

THE NEW PHYSICAL EDUCATION.

IN THE LANCET of Jan. 31st we published an address on physical training delivered before the Royal Society of Medicine by Surgeon Commander K. Digby Bell, of the Royal Naval School of Physical and Recreational Training, Portsmouth. In the course of this address he quoted a scheme elaborated by Commander B. T. Coote, in which activity, energy, and character were developed by physical, recreational, and moral training. On Feb. 19th, at the Royal Sanitary Institute, under the auspices of the Child Study Society, Commander Coote himself delivered a lecture on Physical Education and its Relation to National Ideals, in which he showed how the system could be applied to the promotion of the health and character of a people. Physical education, he said, was a science not sufficiently developed or understood in this country, and, although school prospectuses called attention to the teaching of physical culture and drill, parents had not troubled to find out in what its virtue consisted. A boy might bring home a silver cup—and incidentally a spinal curvature—but nothing had been done to study his physical well-being from a scientific point of view. Commander Coote showed on the screen some of the evil effects of the uncontrolled physical exercises encouraged in some schools—boys with round shoulders, hollow spines, flat chests, and pot-bellies. It was the duty of the physical trainer to prevent these deformities. By means of diagrams drawn from individual cases he showed the evil effects of certain collars in preventing head and chest movements, the tendency to curved spine as the result of carrying ooks under one arm with the opposite hand in the pocket, nd various unhygienic reading, writing, and sleeping ostures. These indicated the need for continuous physical raining. Any existing weakness should be corrected at nce, lest it should increase later and lead to serious trouble. escribing the ingenious and effective method of teaching wimming in the navy, he said that the real work was done n dry land. The positions assumed in the breast stroke vere analysed into four collective movements, and these vere shown in diagrams at the end of a large hall. The men aid themselves on a sort of bench, and with their eyes fixed n the diagrams carried out the movements until perfect. hey were then given a life-saving belt so constructed that when in the water the swimmer assumed the proper posiion. Many men could swim ten lengths of the bath at their first attempt with this belt, which is removed as soon as knowledge and confidence have been attained. The number of lessons necessary average from eight to nine.

---

[1] Being a portion of a paper read before the Royal Society of Arts on Feb. 13th.

Some of the physical exercises used at school were destructive in their effects—he instanced certain uses of the parallel bars—but with the help of the medical profession this fact could be demonstrated to those in charge, and the exercises forbidden. This country had the reputation of being the most sporting nation as far as games were concerned, but the majority of the people did not play games at all. If we were going to use recreation to develop energy some form of recreation must be found that would appeal to the majority. Fortunately, some 300 games were capable of being utilised for this purpose. He hoped, however, that recreational training would not be the thin end of the wedge for doing away with physical training. Games had necessarily a constructive value. In order to develop character in the pupil the physical educationalist must study the mind. Appeal to the moral side of the boy's character could be made, and instruction with regard to the abuse of his body could be given openly and effectively. Physical training, as he understood it, was a science and a part of preventive medicine. If we treated physical education in such a way as to be of value throughout the country much could be done to prevent industrial unrest.

COLONIAL HEALTH REPORTS.

Bermuda.

ACCORDING to a report prepared by Mr. W. B. Jackson, Colonial Secretary, the resident population, exclusive of the naval and military establishment, has been slowly increasing during the last decade. At the Census of 1911 it was estimated at 18,994. On Jan. 1st, 1919, it was computed at 21,840—7433 white and 14,397 coloured.

The birth-rate during 1918 was 27·10 per 1000—21·63 among the white population and 29·93 among the coloured. The illegitimacy rate was 2·3 per 100 births among whites and 18·6 per cent. among coloured persons. The death-rate of 14·37 per 1000 among whites and 24·10 per 1000 among the coloured population was higher than usual, being affected by an outbreak of Spanish influenza in September, which was responsible for about 125 deaths amongst about 5000 cases. There has been no recrudescence since the outbreak. The great majority of deaths from influenza occurred among the coloured population and were attributable in some cases to failure on the part of the patients to observe proper precautions, and in others to enfeebled physical condition, such as pre-existing tuberculous tendencies. It is many years since the islands have been visited by an epidemic of so severe a character; and the unusually favourable health conditions normally prevailing intensified the impression caused. The colony is blessed with natural conditions of climate and geographical position which should make it one of the healthiest spots in the world. Except for a period of about three months during the summer, when the atmosphere is especially humid and conditions somewhat enervating, the climate is remarkably agreeable and mild. Free from extremes either of heat or cold, and situated in mid-ocean with no land nearer than 500 miles, the islands offer the conditions of air and atmosphere prevailing on a very large ship in temperate latitudes, with none of the discomforts attendant on a sea-voyage. Their freedom from serious infections is due largely to these conditions. The rainfall during 1918 was 64·16 inches, being some 8 inches above the average of the preceding nine years. Rain fell on 155 days, being most frequent and heaviest in November and April. The highest temperature recorded was 88·8° F. on August 14th, and the lowest 48° on Feb. 6th. Mean relative humidity was 88°.

British Guiana.

The Registrar-General's estimate of the population of the colony on Dec. 31st, 1918, was 310,972 (161,693 males and 149,279 females).

The birth-rate for 1918 was 25·1 per 1000, compared with a mean rate for the previous five years of 31·0 per 1000. Of the births registered 3401, or 43·7 per cent., were legitimate, and 4390, or 56·3 per cent., illegitimate. The birth-rates of the several races representing the community were, per 1000 of the estimated population, as follows: Portuguese, 23·1; Europeans other than Portuguese, 12·2; East Indians, 23·3; Chinese, 31·7; blacks, 25·2; mixed races, 27·0. The death-rate was 40·6 per 1000, as against 30·4 in 1917 and 27·1 in 1916. The death-rate of the various races was: Portuguese, 35·3 per 1000; Europeans other than Portuguese, 13·5; East Indians, 49·4; Chinese, 28·2; blacks, 35·7; mixed races, 25·0. Enteric fever is a notifiable disease, and in 1918 637 cases were notified with 129 deaths. Anti-malaria and anti-mosquito measures are being generally and gradually enforced, with visible signs of success. Ankylostomiasis, which has engaged the attention of the Medical Department for several years, has considerably decreased on the sugar estates; this is attributed to improved sanitary measures and the erection of latrines. There are five public hospitals in the principal centres of population, and the outlying districts are served by dispensary hospitals and dispensaries. The immigration law also requires the maintenance of hospitals on every plantation on which there are indentured East Indian labourers, and those institutions are available for the treatment of emergency and pauper cases from the general community. There were 479 patients in the public hospitals at the beginning of 1918, and 15,890 were admitted during the year; the deaths numbered 2072. Outdoor treatment was given to 52,954 persons. At the Leper Asylum there were when the year began 212 males and 82 females. During the year 79 were admitted.

East Africa Protectorate.

The report respecting the affairs of the Protectorate for the year 1917–18 estimates the total population at 2,651,771, made up of 5362 Europeans, 14,693 Indians, 2126 Goans, 7358 Arabs, 69 of other races, and 2,622,163 natives.

The general health of the country was exceptionally good. Malaria, as usual, was common everywhere, and few districts escaped dysentery and the occurrence of sporadic cases of smallpox. The desert areas suffered notably from beri-beri. A small epidemic of influenza was reported from Meru. Plague reappeared in Mombasa on April 25th, 1917. Further cases were discovered on May 19th, and it appeared at intervals in various localities subsequent to that date. Of the 101 cases recorded, 84, with 78 deaths, were among the uninoculated, and 17 cases, with 10 deaths, among those who had received prophylactic protection. In Nairobi the case-incidence was somewhat higher. The disease originated in the Indian bazaar, and spread rapidly to other quarters of the town and to the native villages on its perimeter. 20,776 rats were caught, of which 37 were found to be infected. The total number of inoculations against plague was 100,214, as against 18,273 in 1916 and 6878 in 1915. 796 cases of cerebro-spinal meningitis, with 615 deaths, were reported from 12 districts extending from the coast to Lake Victoria. This is a considerable increase over every year since 1913. 2613 cases of dysentery were observed, with 160 deaths. In addition to these the medical officers of health have reported 2559 deaths from dysentery and diarrhœa in the townships of Mombasa, Nairobi, and Kisumu.

A NURSES' CLUB AT BRIGHTON.

"THE first of its kind to be established in the United Kingdom" was a remark made by Sir Arthur Stanley at Brighton on Feb. 21st, when he opened, at 45, Marine Parade, a residential club for nurses, in connexion with the Brighton and Hove Centre of the College of Nursing. Edinburgh and Dublin are copying the example of Brighton, and Sir Arthur Stanley expressed the hope that ere long he would be able to say the same of London. The Brighton Club permits of accommodation for 15 nurses, and the premises have been loaned free until 1927 by the owner, Mr. C. R. Scrase Dickins. Dr. E. Hobhouse (one of the senior physicians), Miss Kathleen Scott (matron), and Miss Latham (under matron), of the Royal Sussex County Hospital, hold the respective offices of chairman of the finance committee, chairman of the executive committee, and honorary secretary and treasurer.

SMELLS AT LOWESTOFT.

PROVISION is made under the Public Health Act of 1875 to deal with objectionable smells or effluvia arising from the process of manufacture. The Lowestoft Fish Meal and Cake Company was recently prosecuted under Section 114 of this Act for carrying on the manufacture of meal and manure from fish offal in such a way as to cause effluvia which were a nuisance to some of the inhabitants of the town. In November, 1918, this company applied for permission to establish a factory under Section 112 of the Public Health Act, which provided that if an offensive smell occurred heavy penalties would ensue. Permission was not granted, in spite of which the factory was opened without consent in July, 1919. The corporation recently received a memorial complaining of the nuisance from 34 residents living near the factory, in consequence of which the sanitary authority brought this prosecution.

Evidence was given before the magistrates by the sanitary inspector for the borough, who stated that the fumes which came from the factory were of a sickly nature and filled the atmosphere. He said he was not satisfied with the way in which the plant was worked inside the factory, and thought the nuisance could be abated if the plant was altered and the fire allowed to consume the fumes. Dr. A. Marshall, medical officer of health, said that in his opinion there were good grounds for the complaint, as the smell was unbearable. He considered that if the fumes were passed through a condenser and the chimney heightened to 60 feet the nuisance would probably cease. Several residents gave evidence as to the disagreeable nature of the effluvia from the manufacture. The firm stated, through their solicitor, that they had no wish to cause a nuisance, and asked the magistrates to adjourn the case in order that various alterations could be made. They suggested that a 2000-gallon tank should be attached to the condenser and the fumes passed through the tank and sprayed. This suggestion was agreed to.

HOSPITALISATION OF INFLUENZA.

THERE is a growing feeling in America against the removal from their homes of patients suffering from influenza. A recent bulletin of the Chicago School of Sanitary Instruction contains a manifesto by Dr. J. D. Robertson to the physicians of Chicago in which he says:—

> I am convinced that in the present outbreak of influenza the wise and proper thing to do is to insist upon home treatment and care of influenza cases, rather than hospitalisation. Only such cases should be hospitalised as cannot possibly be taken care of in the home.
>
> There is a large element of risk in taking a patient with a temperature from a warm bed and room into an unheated ambulance and transporting such patient several miles to a hospital, where probably another long wait must be endured before finally being comfortably provided for. This procedure greatly increases the chances of pneumonia complications.
>
> I think it will be found that most influenza cases can be taken care of in their homes with much better chances of recovery than would be afforded by removal to hospitals. The Department is doing all it can to supply nurses to families where there is the most urgent need. I have had many requests for nurses in homes where there were well members of the family and probably one or more servants who could take care of the sick, and in such cases we have declined to furnish nurses in order to husband our supply for cases where those who are sick are unable to get nursing care of any kind.

Dr. Robertson concludes by urging the Chicago physicians to coöperate with the Health Department in advising home care of influenza patients in all cases where it is possible.

SUMMER-TIME, 1920.

SUMMER-TIME will commence this year on Sunday, March 28th, and end on Monday, Sept. 27th.

THE RANGOON BEAN.

IN the village of Lankwitz (Brandenburg) an epidemic of diarrhœa and vomiting has occurred with great physical depression following, ascribed to the use as a food of *Phaseolus lunatus*, known in commerce as the Rangoon bean, and now entering Germany in large quantity. Professor L. Lewin, of Berlin, attributes the symptoms to HCN poisoning. In France, it is stated, the import of these beans is only allowed when 100 g. yield less than 20 mg. of HCN.

THE DE-DOMESTICATION OF THE RAT.

IN the course of a lecture on Tropical and Subtropical Diseases delivered recently before the Royal Colonial Institute Dr. Louis Sambon stated that experience has shown again and again that rat extermination is practically impossible. He proceeded: "It may have been otherwise at the time when, according to that distinguished Spanish canonist Azpilcueta of Navarre, rats exorcised and ordered to depart for foreign countries, would obediently march to the coast in large bodies and thence swim off in search of desert islands where they could enjoy life without annoyance to man. Unfortunately, rats can no longer be exorcised or rhymed out of existence. In India rats are as plentiful as ever, notwithstanding the enormous destruction carried out since plague broke out. No better results were obtained in Japan where the campaign was carried out with a thoroughness characteristic of the Nippon islanders. The slaughter only renders conditions more favourable for the multiplication of the survivors. The increased mortality is met by increased birth-rate, and, as every one knows, the rat's breeding powers are incredible. Five to 10 litters in a year, 6 to 20 young in a litter, and the young able to breed in less than three months! Besides, what would be the use of destroying rats unless we made adequate provision to prevent more rats from landing? Every ship brings rats, especially grain ships, a thousand and even 1700 rat carcasses have been counted after fumigation of a single ship and thousands of ships reach our ports. What we can and should do is to render our wharves, quays, markets, store-houses, and other public buildings rat-proof. The rat must be entirely excluded from occupied buildings. He must be de-domesticated, if I may use the expression—he must be built out of existence—as Surgeon-General Blue tersely puts it. Attracted by food and cover, he has overcome every fear of man and imposed himself upon us as an effronted and dangerous commensal. The proper storage of food, the immediate removal and burning of all food-wastes, garbage, and rubbish, the destruction of places in which he may find harbourage, and the contrivance of architectural modifications apt to cut off his approach, the liberal use of concrete, wire netting, and sheet metal will certainly discourage him."

Dr. Sambon points out that the agency of the rat in the dissemination of plague was well known in ancient times. Our ancestors carefully protected and, when possible, domesticated the natural enemies of the rat and even deified some of the more useful ones, as the cat, the kestrel, and the cobra. They made special use of rat-eating species of snakes, kept great numbers of these harmless snakes in specially constructed pits in their medical temples, and sent them to be liberated wherever the disease had broken out. Thus in the year 293 B.C., Rome being ravaged by the plague, the Tribune Quintus Ugulgius went to Epidaurus at the head of a commission to ask the priest-physicians of the famous Asklepion temple what should be done to check the pestilence that was devastating the city. They brought back with them rat-eating snakes, and these soon put an end to the disease; after a time the snakes died out, but the people long continued to paint their effigies on the walls of the lararium in token of gratitude, and paid them the tribute due to protecting household gods.

MILK OF GOOD QUALITY.

IN the case of a prosecution for selling milk deficient in milk fat, which took place recently in the Isle of Wight, a novel and rather ingenious point was raised, owing to the police sergeant who purchased the samples analysed having asked the defendant for "a pint of new milk of good quality." It was contended by the prosecution that this should deprive the defendant of the defence, established by the case of Hunt *v.* Richardson, that the milk was sold by him as it came from the cow. After considerable discussion upon questions arising out of the analysis, the bench were satisfied that the milk sold was deficient in milk fat to such an extent that the defendant should be convicted, and further held that it had not been proved by the defence to have been sold as it came from the cow. In these circumstances they did not go into the other point referred to. It seems likely that if they had done so conviction would have followed, whether the milk had been proved to have been sold as it came from the cow or not. Milk not up to the standard laid down for new milk could hardly be deemed to be "of good quality." Whether straight from the cow or not it would not be of the nature and quality demanded. Unfortunately, however, the ordinary housewife or purchaser is not likely to specify "good quality" when buying milk, and the farmer or dairyman of whom such a demand was made, either by a private customer, or more particularly by an official, would be likely to scent a trap. He did not apparently do so in the case under discussion, but it would be a natural and reasonable reply for him to make if he said, "It is new milk," or "It is milk as it came from the cow"; in the subsequent event of analysis being against him the defence that the milk, whatever its quality, had not been tampered with would be open to him.

THE SMALL-POX MENACE.

To the Editor of THE LANCET.

SIR,—With reference to your annotation in THE LANCET of Feb. 7th with the above title, I note that you say there were 63 cases in England and Wales for the year 1918. According to the analysis of sickness statistics for London for the year 1918 (THE LANCET, April 12th, 1919) there were 35 notified cases in London. That makes over 50 per cent. of the cases occurred in London. In a letter from Dr. A. F. Cameron in THE LANCET of June 22nd, 1918, on small-pox in London he stated that for the first six months of 1918 there were 41 cases in London. I suppose these varying returns can be reconciled. For 1919 the total number of cases in London, according to the monthly analyses published in THE LANCET, was 26 (January, 7; March, 7; April, 2; May, 3; June, 2; and July, 5). In the first half of the year 1919, according to your latest annotation, there were 208 small-pox cases in England and Wales, so that it is obvious that in 1919 London had nothing like 50 per cent. of the cases, which is good for London. Dr. Cameron in his letter contended that the maximum intensity of small-pox in London was every nine years from 1884—that is, 1884, 1893, 1902, 1911—and added, "It seems reasonable to expect that in 1920 another maximum will be recorded." It will be interesting to learn later whether the expectation is fulfilled.

I am, Sir, yours faithfully,
ZIGZAG.

London, Feb. 10th, 1920.

H. P. U. (U.S.A.).—Under the late Turkish administration doctors possessing foreign diplomas, who were not Turkish subjects, had to pass a viva voce examination at Constantinople, conducted in French or Turkish, in order to obtain the Government diploma entitling them to practise in Palestine or any other part of Turkey. Presumably there will now be some local substitute for this obligation, although nothing appears at present to have been settled. Openings for practice in Palestine are limited. Jerusalem is overdone with medical institutions, and nose and throat specialists were already practising in Jaffa and Jerusalem before the war. An American medical man might work up a small consulting practice in such a growing centre as Haifa. In the future, as in the past, the main part of the medical work will be done by Jewish doctors ministering to their own people.

Lettsomian Lectures

ON

TUMOURS COMPLICATING PREGNANCY, LABOUR, AND THE PUERPERIUM.

Delivered before the Medical Society of London on Feb. 2nd and 16th, and March 1st, 1920,

By HERBERT R. SPENCER, M.D., B.S. Lond., F.R.C.P. Lond.,
OBSTETRIC PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL.

LECTURE III.[*]

Cancer of the Uterus Complicating Pregnancy, Labour, and the Puerperium.

The rarity of the combination of cancer of the uterus with pregnancy is shown by the fact that few gynæcologists have published even such a small list (10 cases) as that which I have been able to collect among my own cases. Even then the cases have not been all personally treated by the authors, but are often the collected cases of clinics published in inaugural dissertations and theses, the writers of which are inexperienced and are wanting in the intimate knowledge which only personal attendance can give. In the clinic of Professor Wertheim, who has had such an extensive experience of this disease, amongst 250 cases of cancer of the cervix only 6 were complicated with pregnancy, and some of these were not treated by the professor. The largest series attended at one clinic I have been able to find is that published by Glockner,[1] consisting of 17 cases from the Gynæcological Clinic of Zweifel at Leipzig, followed by a series of 10 cases from the same clinic by Aulhorn.[2] In 1904 Sarwey[3] had been able to collect from the literature only 240 cases of this complication which had been subjected to operation, and he states that v. Winckel had met with 10 cases in 20,000, Stratz 7 in 17,832, Sutugin 2 in 9000, Glockner 17 in 26,000, Orthmann 6 in 4028, Doderlein 7 in 5001, the Rostock Clinic 4 in 2287 labours, and gives the frequency as 1 in 1600 labours.

Discussion of Cases.

In Tables E and F are given brief particulars of the 10 cases of cancer of the cervix complicating pregnancy, labour, and the puerperium, which I have had under my care at University College Hospital. They comprise all the cases I have seen; I have not met with a case in private practice.

Cases 5, 6, and 7 have been published with full details in the Obstet. Soc. Trans., Vol. XLVI., for 1904. A few notes here will bring the after-histories up to a later date. In all these cases the growth was a squamous-cell carcinoma.

Case 5 (see Table F, No. 1).—E. W., aged 33 (children 4, abortion 1), was delivered on March 25th, 1893, by forceps through a cancerous cervix, of a full-term living child, which died of whooping-cough when 11 months old. The labour was slow. The patient had had a discharge of blood for eight months. There was no post-partum hæmorrhage. On April 8th, 1893, high amputation was performed with the Pacquelin cautery. On June 6th, 1894, she became pregnant in the body, which had been left behind. On March 6th, 1895, I delivered her by Cæsarean section, terminated as a Porro's operation, with extra-peritoneal treatment of the stump. This child grew up and served as a soldier in the Great War. In 1918, 25 years after the high amputation, the mother was examined by me and found to be in excellent health. (Figs. 1 and 2.)

Case 6 (see Table F, No. 2).—A. C., aged 35 (children 8, abortion 0), was admitted to U.C.H. on Jan. 3rd, 1896, when seven months pregnant. She had had hæmorrhage on coitus for seven months, and a thin, watery offensive blood-stained discharge for six months. There was a large cancerous growth on the posterior lip and left side of the cervix. Labour was induced by de Ribes's bag: the child (3 lb. 7 oz.) lived only 38 minutes. On Jan. 28th, 1896, I removed the cervix by the high amputation with the Pacquelin cautery. I have seen this patient many times since the operation. I examined her in 1918, 22 years after the operation, and found her free from recurrence and in excellent health. (Figs. 3 and 4.)

Case 7 (see Table F, No. 3).—M. S., aged 38 (children 9, abortion 0), was delivered in the maternity of U.C.H. on Jan. 25th, 1896, naturally, of a living child. She had had no bleeding during the pregnancy, but blood and shreds were passed every day afterwards. On June 5th, 4 months and 11 days after delivery, she was examined and found to have cancer of the cervix. High amputation was performed on June 30th, 1896. In 1915, 19 years after the operation, I examined the patient and found her free from recurrence and in excellent health. The child lived at least to the age of 8 years. I have no further note about her, and her mother's present address is unknown. (Figs. 5 and 6.)

Age of the Patients.

Of the 10 patients, 2 were between the ages of 20 and 30; 7 were between the ages of 30 and 40; and 1 was between the ages of 40 and 50. The youngest patient was 26, the oldest 40.

In dividing patients according to decennia "20–30," &c., a patient aged 30 should appear in the 30–40 list; some writers erroneously put the patient in the 20–30 list, and thus the statistics may be misleading. Sarwey's patients were divided into 20–30, 31–40, 41–50, which is not a decennial division at all. Of his collected series of patients, 17·8 per cent. were between 20 and 30; 64·4 per cent. were between 31 and 40; and 17·8 per cent. were between 41 and 50. Sarwey shows from the ages of 3442 cases not complicated with pregnancy that only 3 per cent. were between 20 and 30; 22·4 per cent. were between 31 and 40; 34 per cent. were between 41 and 50.

The figures show that in the child-bearing period of life cancer uncomplicated with pregnancy is at its maximum in patients over 40, but when complicated with pregnancy under 40; and that below 30 the frequency of cancer is six times as great in the pregnant as in the non-pregnant. The youngest of my patients was 26 years of age. I have never met with cancer of the cervix at an earlier age than this. Of Sarwey's collected cases the youngest (Schwarzwaller's) was only 22, the oldest was 47.

Number of Children and Abortions.

Cancer of the cervix is very rare in women who have not been impregnated. Olshausen and Döderlein have published cases of cancer complicating the first pregnancy. Cancer even in the second pregnancy is rare, having been found only six times in Sarwey's 180 cases. To these may be added my Case 3. My 10 cases had had in all 70 children and 11 miscarriages—that is, an average of 7 children and over 8 pregnancies. Six out of the 10 patients had had 8 children, and half of them had had 9 or more children, the greatest number of pregnancies being 15 (Case 9). The influence of multiparity is thus shown, as in all the statistics dealing with this combination.

Why cancer of the cervix should be almost confined to parous women and so extremely rare in virgins is a question which has been much discussed. Lacerations during labour and abortion have been supposed by many to be the causes of the development of cancer in this situation. Observations on this point are few in number;

6	34	10	1	8th	L.	D. (7 mths. later).	L.	D. (15 days later).	Per abdomen, by Porro-Cæsarean section, with use of serre-nœud.	No; too far advanced for curative operation.

[‡] In the eighth or ninth calendar month. [5] After high amputation of cervix (see text). [6] Of whooping-cough.

but Sir John Williams has published a striking case where the laceration was the only part of the os not affected. It seems probable that lacerations, by exposing the cervical mucous membrane to external irritation, may tend to favour the development of cancer, but its influence is probably small; for cancer often develops in cases in which there is no sign of previous laceration, and in situations where lacerations do not occur: and, moreover, cancer of similar structure occurs in the body of the uterus in which the question of laceration does not arise.

Dr. King, of Washington, propounded a theory that the development of cancer was set up by the influence of spermatozoa in giving rise to multiplication of the epithelial cells, under certain conditions, in the same way as they cause development of the cells of the ovum. Erosions have been thought by some to be a pre-cancerous condition, and very radical methods of treatment have been suggested in consequence. As erosions are very common in virgins, in whom cancer of the cervix is met with extreme rarity, it is quite certain that erosions rarely develop into cancer. Nevertheless, in erosions are sometimes found both metaplasia and hyperplasia, and even slight downgrowth of the epithelium, which renders the differential diagnosis from early carcinoma occasionally difficult. And to the naked eye a case of this kind sometimes shows papillary, club-like, or finger-like processes, or even extensive papillomatous growths which may closely resemble cancer. These growths are, I think, sometimes the result of excessive sexual irritation and of venereal infection. And I am inclined to think that when the question of the causation of cancer of the cervix is solved it will be found that the reason why this disease is almost limited to women who have had coitus is that local venereal infection is almost limited to them. I do not know of a series of scientific investigations into the relations of syphilis, soft sores, and gonorrhœa to cancer of the cervix, but I believe it will be found to be a close one. I have twice seen cancer of the cervix develop in patients who had previously had a chancre of the cervix.

Influence of the Cancer on the Pregnancy.

Cancer of the cervix by obstructing the canal, by the hæmorrhages and discharges to which it gives rise, and the infection and inflammation which often accompany it, tends to prevent the occurrence of pregnancy, and when it occurs to produce abortion or premature labour. Of my 10 cases 2 aborted spontaneously at the fifth and sixth month. Case 3 died undelivered, from coma, probably due to syphilitic brain disease, possibly to renal disease from pressure on the ureters. Case 4 was operated on at the fourth month. Of the remaining 6 cases 4 were delivered prematurely at the eighth calendar month; one of these was induced; the other two were at term. Both the cases which aborted were septic on admission to the hospital, and it is probable that the infection brought on the abortion. Apart from this there does not appear to be a great tendency for abortion to occur in the early months. Of the 6 cases of pregnancy in the eighth and ninth calendar months, in no less than 3 labour came on prematurely, which seems to show a great tendency to premature delivery.

The growth may in some cases be so extensive as to prevent the delivery of the child, and "missed labour" may occur. In Case 9 the uterus ruptured during labour.

It is to hæmorrhage, sepsis, and rupture of the uterus that the high mortality of this complication is due.

Influence of the Pregnancy on the Cancer.

The influence of the pregnancy on the cancer has been varied in different cases. Zweifel's case, in which the growth extended by two fingers' breadth in the course of a fortnight, has probably attracted unusual attention from the method employed to estimate the rate of growth, viz., passing a thread through the edge of the growth—a procedure not altogether free from risk! In Case 9 the growth apparently did not alter in size at all during nearly two months' daily observation. After the labour it diminished at first, but began to increase about two months later. The three cases (8, 9, 10) which were inoperable survived from 7 to 12 months, which does not show any marked rapidity of growth after delivery, seeing that in all the cases the growth had reached an advanced stage at the time of delivery, which was difficult (forceps, Cæsarean section, forceps for rupture of uterus).

Symptoms.

Of the three chief symptoms of cancer of the cervix, hæmorrhage, discharge, and pain, the most important is the hæmorrhage. When the cancer complicates pregnancy the hæmorrhage may lead the patient to think she is not pregnant or has miscarried.

Hæmorrhage as the result of coitus is a symptom of the greatest importance. It occurred as the first symptom in Case 6, and was followed by a characteristic thin, watery, offensive, blood-stained discharge, which, after it had existed for six months, led the patient to seek advice. In some cases, however, the growth does not bleed as a result of pressure upon it. An instance of this was Case 9, and Kreps[4] has published a similar one. In some cases the hæmorrhage occurs at approximately monthly periods, and thus leads the patient into error with regard to the presence or duration of pregnancy.

The second cardinal symptom, discharge, is often the first in point of time, but is unnoticed by the patient, owing to the frequency with which it occurs from other causes. When, however, it is watery and discoloured, or blood-stained, it should at once arouse suspicion; an offensive discharge is due to necrosis, and often occurs only in the later stages of the growth.

The third cardinal symptom, pain, ordinarily does not occur in cancer of the unimpregnated uterus until the growth has extended beyond the organ; occasionally inflammation resulting from bacterial infection will cause it to appear while the growth is limited to the cervix. In cases complicated by pregnancy, pain may occur at an earlier date, being due to contractions of the uterus or to a threatened or actual abortion, as well as to septicæmic infection, which is very prone to occur in these cases (1 and 2). The secondary symptoms—wasting, malaise, cachexia, pressure symptoms—do not differ from those met with apart from pregnancy.

Diagnosis.

Cancer of the uterus complicating pregnancy always affects the cervix: there is, so far as I know, no case recorded of cancer of the body complicating pregnancy which will stand investigation. The cases formerly published were either cases of chorion-epithelioma or sarcoma. In making the diagnosis, three methods are employed (*a*) digital pelvic examination, (*b*) inspection, and (*c*) microscopical examination. In the early months it may be difficult to make out the condition of the pregnant uterus on account of the presence of the growth and the bleeding to which bimanual examination may give rise. On the other hand, the uterus is not rarely distended by pus (pyometra) in cases of cancer of the cervix, and it may then closely simulate a pregnant uterus, especially if menstruation has stopped. This will rarely occur apart from pregnancy until the age of the menopause (47), and pregnancy at this age is so exceedingly rare that only one case was recorded in Sarwey's collection.

On vaginal examination either a growth or an ulcer will be felt, both differing markedly from the normal cervix by being comparatively hard and brittle, breaking down under the finger, and bleeding on pressure with the finger or the point of a sound. In later stages the uterus may be fixed by inflammation or growth in the cellular tissue; this is most easily made out by rectal examination.

On inspection through a speculum—a large Fergusson speculum, with the patient in the lithotomy position, is best for this purpose—an irregular growth with nodular or club-like processes, with or without ulceration, may be found. The colour of the growth is livid red, often sloughy on the surface, and may contrast with the purple colour of the vaginal cervix. The surface of the growth should be dried with absorbent cotton-wool, the overhanging edge noted, and the bleeding and breaking down on pressure. If ulceration be present the only conditions likely to be mistaken for it—viz., tubercle and syphilis—are rare.

In some cases only a hard, smooth enlargement of the cervix is met with; there is neither a projecting irregular breaking-down growth nor ulceration, the growth being in the wall of the uterus. In these cases the finger is easily passed into the cervical canal and recognises the bleeding growth. A piece of this should be removed for microscopical examination in all cases. This is rendered especially necessary as the syphilitic and tuberculous affections cannot be distinguished by clinical methods, but are easily recognised under the microscope.

In ordinary cases the diagnosis of the growth is quite easy; the marked contrast of the brittle, bleeding growth with the soft tissues of the cervix of pregnancy leaves no doubt. There are, however, certain diseases of the cervix which closely resemble cancer and certain cases of cancer which lack the usual signs.

CONDITIONS RESEMBLING EARLY CANCER OF THE CERVIX.

Hypertrophied papillary or nodular erosions, hypertrophied and inflamed glandular erosions, and papillomata (simple and diffuse) may closely simulate cancer.

By hypertrophied papillary or nodular erosion I mean a growth with club-like processes or lobules made up of thick connective tissue centres, often containing dilated glands, covered with a single layer of columnar or cubical epithelium. I have not met with this form during pregnancy, but the diagnosis would be difficult without microscopical examination. This form, however, is not friable.

By hypertrophied and inflamed glandular erosion I mean a granular condition similar to the ordinary glandular erosion, but much larger and more vascular; it sometimes measures as much as 1½ in. across, and can be broken into with the point of a sound and bleeds readily on examination. It dose not break down to the extent that cancer does, and the growth does not project from the surface, but in some cases it is necessary to excise a piece in order to exclude cancer. I have not met with this condition in pregnancy, but in the unimpregnated uterus have several times mistaken it for cancer until the microscope showed its nature.

Papillary growths are met with in several forms. The pedunculated papillomata of gonorrhœa are occasionally found on the cervix, but rarely, I think, without being present on the vulva or vagina. This scattered distribution is an aid in diagnosis. Broad flat papillomata with a finely granular surface may be met with both in gonorrhœa and soft sores, and, I believe, as a result of masturbation. They bleed and break down under the finger, are generally softer and more friable than cancerous growths, and can often be pinched off the surface of the cervix with a forceps, leaving a raw red surface, fairly smooth and bleeding freely. Under the microscope a central vascular stem supported by connective tissue is seen surrounded by a mass of large epithelial cells, often œdematous or vacuolated.

Also there occur occasionally more solid isolated polypoid or sessile nodules in the cervical canal and at the external os which consist of stroma of the cervix covered by many layers of squamous epithelial cells (metaplasia of cervical columnar epithelium). In the substance of these growths gland spaces may be cut across of which the epithelium has also undergone metaplasia, so that the spaces are filled with squamous epithelium. If these growths be cut without the subjacent and adjacent tissue, the appearance is not distinguishable from squamous-cell carcinoma, although a deeper section shows no such invasion of the deeper tissue of the organ as occurs in true carcinoma. In excising a portion of the cervix for microscopical examination a wedge-shaped piece should be removed, including the edge of the suspected growth, and after the wedge has been excised care should be taken that the microscopic sections are cut vertically to the free surface and not parallel to one side of the wedge.

Lastly, I would like to direct attention to the unusual features of Case 9 which led to an erroneous diagnosis. The peculiar features were (1) the smooth surface of the growth pitted by several holes from which a pus-like fluid escaped in considerable quantity; (2) the growth did not bleed at all, although it was dressed almost daily for nearly two months; (3) the growth did not break down under moderate pressure; (4) it did not, apparently, increase at all during two months' observation, and in the puerperium at first diminished in size. I do not remember to have seen another case of cancer of the cervix in which these "pus" holes were present, although I have seen several in cancer of the vulva. In this case it is to be regretted that a piece was not excised; this would at once have shown that the growth was a columnar-cell carcinoma and that the "pus" was the liquefied central epithelial cores.

---

[4] Ueber Komplikation der Gravidität mit Uteruscarcinom, Inaug. Dis., Berlin, 1905, p. 35.

Importance of Clinical Examination.

Although the microscope is of the highest value and is indispensable for the diagnosis of certain cases, clinical examination is also of great importance. For want of this I have known a distinguished pathologist decide, as the result of the examination of a microscopical section, that only normal cervical glands were present when clinical examination showed a deeply-invading cancer. In this case the rare form of the cancer—"carcinoma adenomatodes"—in which the glands are lined with a single layer of columnar epithelium would have led to a serious error if reliance had been placed on the microscopic examination alone and the clinical signs had been neglected.

A SURVEY OF OTHER PUBLISHED RECORDS.

Tables of cases of cancer of the cervix in "Advanced Pregnancy"[5] treated by vaginal or combined abdominal and vaginal operation from the papers of Glockner (10 cases), and Olshausen and Kaussmann (8 cases) have been published by the lecturer in the Obstet. Soc. Trans., Vol. XLVI., pp. 369, 371. Of these 18 cases 12 were operable, and gave immediately two maternal and four fœtal deaths. One mother treated by vaginal hysterectomy 17 days after labour survived for five years—Olshausen's case ($5\frac{3}{4}$ years). The final result to the children was not given, but the immediate mortality was five.

Five cases were "inoperable" and were treated by Cæsarean section or Cæsarean hysterectomy with intra-peritoneal or (in 1 case) extra-peritoneal stump. Of the 5 mothers 4 died, and the fifth survived only five months. Of the 18 cases, operable and inoperable, 1 was cured; the total immediate mortality (in all cases operable and inoperable) was 6, or one-third, the operation mortality 3, or one-sixth.

E. Aulhorn[6] has published a series of 10 cases from Zweifel's clinic showing the results of abdominal hysterectomy for cancer complicating pregnancy. Three of the patients were in the last month of pregnancy. One died of pulmonary embolism on the ninth day after the operation; the second recurred within six months; the third was free from recurrence after "a good five years" (no dates or details of the cases are given)—i.e., of the cases in advanced pregnancy a third were "cured." Seven of the patients were in the early stages of pregnancy (up to the eighth lunar month); of these, two recurred (after six months and two years) and five remained free from recurrence for from two to three and a quarter years.

E. Wertheim[7] gives a list of six cases from his clinic. One of these was advanced in pregnancy, but was not in labour. The patient remained free from recurrence five years after the operation of extended abdominal hysterectomy (Wertheim). The case was operated on by Micholitsch. Five of the cases were in the early stage of pregnancy (one at the sixth lunar month, one at the fifth month, and in three the embryo only measured 1 to 3 cm.). One of the patients died of embolism on the fourteenth day after operation; in one recurrence took place; the other three patients remained free from recurrence after five years. Thus, four out of six of the cases from Wertheim's clinic remained well after five years. This is, so far as I know, the best result which has ever been obtained in cases of cancer complicating pregnancy.

P. Glarner[8] has published the cases occurring in the clinic of Professor Wyder at Zurich from 1888–1897. There were eight cases of cancer of the cervix, besides one of cancer of the vagina; all the mothers recovered and two children survived. Three of the cases were in advanced pregnancy. All were treated by Cæsarean section, followed by total abdominal hysterectomy, two children surviving. All the cases recurred and died within a few months. Five of the cases were in early pregnancy. Abortion was induced in 2; vaginal hysterectomy was performed in 1 case; abdominal total hysterectomy was begun (apparently not completed) in 1 case, and was completed in the fifth case. Of the 8 cases, 6 were operated on, but none remained free from recurrence.

Trotta[9] gives a case of his own and a list of 26 cases (occurring between the years 1879 and 1905) of cancer complicating pregnancy in the last three months, which had been operated on by Cæsarean section, followed by total abdominal hysterectomy. The maternal mortality was 38 per cent., the fœtal mortality 23 per cent. Of the 15 patients operated on in labour, 8 died and 7 recovered. He compares the operation with vaginal Cæsarean section, followed by vaginal hysterectomy, where the maternal mortality was 17 per cent., the fœtal mortality 44 per cent. The maternal mortality, after the abdominal operation, was thus more than double, while the fœtal mortality was only half that of the vaginal operation.

Sarwey,[10] in 1908, gave a list of 29 cases of the extended Wertheim operation, in all of which the mothers survived; 12 of these were advanced in pregnancy, and 10 of the children delivered by Cæsarean section survived. The final results are not given. This list, of which the first case is Micholitsch's case, already mentioned, has been widely quoted. It certainly looks remarkable, but it must be remembered that it is made up of *published* cases (so far as known to Sarwey) between the years 1900 and 1908; if all the cases which had *occurred* had been published, it would have included Wertheim's case of death from embolism, operated on in 1905, and perhaps others. Only the thoughtless will believe that it represents the mortality of the Wertheim operation, which, in Wertheim's own clinic, had a mortality of 16·6 per cent., and, even when not complicated with the Cæsarean section required in these cases, has a death-rate of about 18 per cent.

FIG. 6. (Case 7.)—Low power. Med. Soc. Trans., vol. xliii.

R. Vitanza[11] published in 1898 a paper on amputation of the cervix of the cancerous uterus during pregnancy. Of 7 cases seen, in 3 the cancer had spread beyond the cervix; these were delivered in 2 cases by the vagina, and in the third by Cæsarean section. In 4 of the cases the disease was limited to the cervix; these were all treated by high amputation of the cervix. The first case, five months pregnant at the time of the operation, had a natural delivery at the eighth month, and subsequently had a second child, without recurrence of the growth. The second case, also five months pregnant, was delivered at the ninth month. The child lived two days; the mother had peritonitis, but apparently recovered. The third case was operated on without a suspicion of pregnancy; the patient went to the ninth month and bore a living

child; the mother was well six months later. The fourth case was six months pregnant. Labour occurred at 7½ months; the child lived and the puerperium was normal. There was no recurrence three months later.

Two years later, in the same journal, Vitanza published a paper on 33 cases of high amputation for cancer. Of these 15 were early cases; only 2 recurred, and 9 remained free from recurrence for 3 to 12 years, and in 6 of these pregnancy occurred from six months to three years after the operation. The Pacquelin cautery was used in all cases after the amputation. The preservation of the fœtus, and the possibility of pregnancy following high amputation, as shown by Vitanza's cases and one of mine, are valuable advantages of high amputation which should not be overlooked in considering the question of treatment.

TREATMENT.

The treatment of cancer of the cervix complicating pregnancy varies according as the case is "operable" or "inoperable" and the child is viable or not. The question of operability is usually decided by the absence of fixation of the uterus and of thickening in the parametric tissue, though operation, both vaginal and abdominal, permits the removal of the uterus in certain cases where these conditions are found. The age of viability of the child may be taken for practical purposes as in the last three lunar or two calendar months of pregnancy, in this paper called "advanced pregnancy," pregnancy of shorter duration being called "early pregnancy." In advanced pregnancy the interests of the child and the large size and vascularity of the uterus introduce special problems of treatment and increase the danger of the operation, which is especially great during the course of labour.[12]

The chief modes of operative treatment which have been employed for cancer complicating pregnancy are by high amputation, vaginal hysterectomy, extended vaginal hysterectomy, abdominal hysterectomy, extended abdominal hysterectomy, and combined abdominal and vaginal hysterectomy.

In the course of the last ten years great advance has been made in the treatment of cancer of the cervix by radium, mesothorium, and X rays, and for the last five years in several of the chief clinics of Europe, operation has been almost entirely abandoned in favour of radiation treatment. This method of treatment would seem to entail some risk to the fœtus, and I am not aware that it has been employed during the course of pregnancy. The patients are on the average younger, and therefore presumably stronger than non-pregnant patients, but the disease is apt to be more malignant in the young. The glands are, however, comparatively rarely affected.[13]

Treatment during Early Pregnancy.

(*a*) "Operable" cases should be operated on at once. The opinion once held that cancer complicating pregnancy was inevitably fatal can no longer be maintained. The best results have been obtained by the extended abdominal hysterectomy, Wertheim's results having been unequalled by any other method. In view of the fact that the glands are rarely affected, vaginal hysterectomy (preferably performed with the cautery) may be employed in feeble or fat patients, as it has a much lower mortality than the abdominal operation, and amputation of the cervix may be performed in early cases of squamous carcinoma, in which there is a desire to preserve the life of the child and the fertility of the mother. During labour or abortion the same operations may be performed if the case is not infected; if infected the whole womb should be removed.

(*b*) "Inoperable" cases. If the case is not accompanied by bleeding or infection the patient should be kept at rest and Porro's operation with the serre-nœud be performed when the pregnancy is advanced. During labour or abortion the case should be treated on general principles with a view of preventing infection, and subsequently treated during the puerperium with the cautery, radium, and X rays.

Treatment during Late Pregnancy.

(*a*) "Operable" cases should be treated by Cæsarean section, followed by extended abdominal hysterectomy. If the patient is in fair condition the operation is indicated equally on the ground of science and humanity. If the patient is feeble or the growth infected it might be preferable to remove the cervix by the cautery and then remove the child by the vagina or by the abdomen, and apply radium after, or without, the removal of the uterus. This procedure would probably be safer to the mother than the performance of abdominal Cæsarean section and the removal of the uterus (or the cervix after amputation) by the vagina, but would involve some increased risk to the child. Vaginal Cæsarean section entails too great a risk of implantation of cancer cells; and no case is recorded in which it has been followed by cure.

During labour the risk to the patient is greatly increased. In the early stages of labour Cæsarean section, followed by the extended abdominal hysterectomy, will usually be the best treatment. But if the labour be advanced and the growth not extensive it may be safer to deliver the patient *per vias naturales*, and afterwards at an early period of the puerperium to treat the diseases by one of the methods mentioned. It is noteworthy that five of the seven advanced cases "cured" were operated on after delivery.

(*b*) "Inoperable" cases should be treated by Porro's operation with the use of the serre-nœud. It has the advantage over the conservative Cæsarean section that it removes the placental site from the risk of infection, and over Cæsarean hysterectomy with intraperitoneal stump that, in case of infection, discharges will readily escape by the side of the wire, which can be placed at any height above the growth, provided the placental site be removed. In the case of a dead or putrid child it would be possible by the Porro method to close the peritoneal wound above and around the uterus before the body of the organ was opened or amputated.

During the puerperium the treatment does not differ essentially from the treatment of cases of cancer in the unimpregnated.

At the present time there is a great tendency abroad to treat these cases with radium, mesothorium, and X rays, a reaction having set in against the extended abdominal hysterectomy on account of its high rate of mortality. The late Dr. Pozzi[14] proposed a restricted vaginal hysterectomy completed by radium therapy in cases of cancer of the uterus. Although such an operation is unsuitable for some cases of cancer during pregnancy, I believe that in the puerperium vaginal hysterectomy, or high amputation performed with the cautery and completed by the application of radium and X rays will be found to give better results than the extensive operations now usually practised.

The three cases of high amputation described in this lecture, which have remained free from recurrence for 25, 22, and 19 years, are instances of the possibility of cure by simple operations, which are free from danger. As far as I know only two other cases of cancer complicating labour in advanced pregnancy are recorded which have remained well for 5 years after operation—viz., Olshausen's (5¾ years), and Von Ott's (8½ years), both operated on by vaginal hysterectomy in the puerperium. Two additional cases in advanced pregnancy have been cured—viz., Micholitch's (5 years) and Aulhorn's (5 years), both operated on by the extended abdominal hysterectomy. The former was in advanced pregnancy but not in labour; no information as to the presence of labour was given in Aulhorn's case. I attribute the result in my cases to the use of the cautery (in two of the cases) and of antiseptic douches, and also to the fact that the operation was performed after delivery when the tissues were involuting.

The rarity of cure of cancer complicating labour in advanced pregnancy seems to justify the republication of these cases with a later after-history.

Sarwey, in Veit's "Handbuch der Gynäkologie," while mentioning the title of my former paper in the bibliography, does not allude to the cases in the text. Perhaps the after-history of Case 5 may lead the next German writer on the subject to consider the cases worthy of mention.

VERTIGO.

ESPECIALLY IN RESPECT OF ITS SURGICAL AND MEDICAL TREATMENT.[1]

BY SYDNEY SCOTT, M.S. LOND., F.R.C.S. ENG.,
AURAL SURGEON, WITH CHARGE OF OUT-PATIENTS, ST. BARTHOLOMEW'S HOSPITAL, LONDON; SURGEON, DISEASES OF EAR, NOSE, AND THROAT, NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, QUEEN SQUARE.

VERTIGO, in its various forms and phases, is a common complaint. We can produce vertigo easily in most normal human beings; many can recall their distress, popularly known as "mal de mer," on more occasions than one. By a variety of ways, such as whirling motion followed by sudden change of rate, we can in normal healthy individuals evoke the sensations and manifestations of vertigo. Syringing the ears in a certain way, the application of hot or cold draughts of air to the region of the ear, the passage of electric currents through the head, can all be made to evoke vertigo.

Certain diseases are accompanied by giddiness or dizziness, forced movements and staggering gait, often associated with nausea or vomiting. Sometimes faintness with clammy sweat and collapse are outstanding features of the reaction set up in the vertiginous state. It is therefore no wonder that the medical observer meets with difficulty in finding the true cause of manifestations for which the patient seeks medical aid.

When nausea and vomiting, staggering, and faintness and collapse are prominent features of the attack, one can quite understand that it is the stomach or the heart that the patient and often the physician suspect or regard as the source of the complaint.

Many patients with vertigo are found to have a high blood pressure. In others the blood pressure is considered to be too low. Some are found to have signs of renal disease, such as would indicate certain forms of so-called Bright's disease. When no definite signs of cardiac, gastric, or renal disease can be discovered recurrence of vertigo may be suspected to be due to visual errors, and the more so when visual disturbances associated with giddiness form a prominent complaint. Some error of refraction, if found, is then corrected. Should attacks recur, it would seem instinctive in many to suspect some obscure disease of the brain, and particularly of the cerebellum, as the probable cause of the symptoms.

When no evidence of disorder of the brain can be discovered and the other organs which I have mentioned have been found to be free from definite signs of disease, the case is then diagnosed as one of aural vertigo, or possibly neurasthenia or petit mal.

The Frequency of Aural Vertigo.

The late Sir William Gowers told me personally that in his extensive clinical experience vertigo was associated with some aural disturbance or disease in 99 cases out of every 100 who consulted him with this complaint. So often is the aural complaint completely overshadowed by the more obvious disturbances, such as vomiting, staggering, or faintness, which distress the patient so much more than any auditory defect, that we can quite realise, as medical men, why the patient believes that the true cause of the complaint is elsewhere.

Gastro-enterostomy has been performed upon patients whose gastric complaint was eventually proved to be due to aural vertigo. I have seen patients suffering from disease of the ear, associated with sickness, whose malady had been erroneously diagnosed and treated as that of gastric influenza, gastric ulcer, or even morning sickness of pregnancy. And yet we are all prepared to agree that those who are subject to spontaneous attacks of vertigo when suffering from gross disease of the ear, such as acute or chronic otitis media, should undergo suitable treatment for the ear disease in the first instance.

I have seen the diagnosis of hysteria made in the case of a patient whose vertigo was associated with a polypus in the ear. The distinguished physician was correct in recognising hysterical manifestations, but he was, I believe, advising erroneous treatment when he recommended that the patient should be treated for hysteria instead of for the aural polypus which had set up the vertigo that led to the hysterical state.

It is common knowledge that wax in the ear sometimes causes giddiness until it has been completely removed. I knew a medical man who, having suffered from giddiness, developed mental troubles and neurasthenia, which prevented his practising his profession for many months, until the removal of a very small cake of cerumen which lay in contact with the lower part of his drum, and which had been disregarded by his former adviser.

It is known that suppuration in the ear may be accompanied by spontaneous dizziness and sickness, until the drum has been incised or the mastoid drained.

Vertigo in Labyrinthine Disease.

It is becoming familiar, certainly to aural surgeons, that chronic infection of the temporal bone may lead to erosion of the labyrinth and set up giddiness, which is cured by removal of the disease in the cavity of the middle ear which produced the erosion of its walls.

It has become recognised that it is the duty of the surgeon to distinguish those cases of erosion of the bony labyrinth without infection from those with infection and destruction of the membranous labyrinth, for he must in the latter case be prepared to follow the disease into the labyrinth by opening and efficiently draining the vestibule and semicircular canals, but should generally withhold his hand if the labyrinth responds to stimulation.

Spontaneous vertigo in the course of active middle-ear disease is often, but not always, an imperative and urgent call for surgical intervention. When the vertigo is rapidly followed by signs which indicate that the labyrinth has become completely defunct, we must recognise that we are in face with those manifestations of infective labyrinthitis which generally lead to fatal basal leptomeningitis if nothing be done.

---

[1] Being the substance of an address read before the Plymouth Medical Society on Jan. 31st, 1920.

We have been able to trace at the bedside the progress of infection from the ear, through the labyrinth to the basal meninges, and so to the post-mortem table. But its fatal progress can be stayed when passing through the labyrinth if we recognise the significance of the giddiness, character of the nystagmus, forced or erroneous directional movements of the limbs. And we have learnt that the patient may be saved from fatal meningitis by timely drainage of the labyrinth.

So much for the value of vertigo as a sign. Even in meningitis, given the case early, by draining the basal meninges through the labyrinth life may be saved. I refer to the operation for meningitis now known as "translabyrinthine drainage," first described by my colleague, Mr. C. E. West, and myself. But the enthusiastic surgeon must beware lest he open a labyrinth in error, for he may thereby cause the fatal disease which he had hoped to avert. I would recommend such to reconsider the inferences to be drawn when he discovers the true signs of completely defunct labyrinth.

Let us neither fall into the error of treating a possible infective labyrinthitis by procrastination, nor, on the other hand, of treating vertigo impetuously by opening the labyrinth before ascertaining whether the signs justify a diagnosis of destructive labyrinthitis.

Menière's Disease.

I wish now to turn to the class of case which is of more direct interest to the physician. I refer to the group of so-called Menière's disease, which is recognised now to be a symptom-complex. It was one of those extraordinary errors handed down by medical traditions to regard Menière's disease as being due to hæmorrhage into the labyrinth. There is no evidence to support this view to which Menière's writings show that he never laid claim. Almost the only circumstance in which hæmorrhage into the labyrinth occurs, and even then very rarely indeed, is that of leukocythæmia in certain cases.

Menière's one and only post-mortem case of vertigo which revealed any abnormal signs was one which we now claim to be recognised as infective streptococcal labyrinthitis with intensely hypervascular membranous semicircular canals which to naked eye resembles a blood clot, but which really consists of inflamed and engorged tissues infected by long-chained streptococci. The commonest variety of Menière's disease proper is a non-hæmorrhagic and non-infective disturbance of the intact and normally reacting labyrinth. This is so in the vast majority of cases which we meet with in ordinary clinical practice. The symptom-complex is easily recognised. There is generally, but not invariably, a certain defect in hearing with tinnitus. (I have seen many with no defect, also an airman with hyperacute hearing and Eustachian obstruction.[2]) Perhaps the attacks occur more frequently after a common cold in the head or influenza and are ascribed by the patient to his or her being "out of sorts" or "run down." Sometimes the patient is the subject of chronic catarrh of the nose or throat, which may have lasted for years and may be associated with dyspeptic disturbances and perhaps hypochondriasis. The onset of vertiginous seizures is apt to be put down to a "touch of the liver," but its mechanism is unexplained. The patient may actually be under treatment for nasal polypi or some other affection of the accessory sinuses of the nose or throat when troubled with dizziness, staggering, and often nausea, but he rarely regards these maladies as being connected with the cause of the giddiness.

There are, again, other individuals who become subject to vertigo who have not suffered from any of the obvious diseases which I have referred to. Sometimes the physician and neurologist are baffled and, having diagnosed aural vertigo, recommend the patient to consult an aurist. Aurists may find only slight defect of hearing, which he regards as slight nerve deafness, or possibly there seems a tendency to Eustachian catarrh. He is uncertain which is the more important, but it seems of small consequence, and the outlook is regarded as unpromising. The patient returns to the physician with the aurist's report, which perhaps recommends that the patient requires general medical treatment, rest and change, combined with bromides, iodides, perhaps minute doses of quinine, and a little nux vomica to try and avert depression. When these measures fail, or when the vertiginous attack is prolonged or persistent, lasting perhaps several days, it is probably agreed that the question of syphilis must be considered.

In my experience it is indeed most important that, whatever the rank of the patient, the blood should be examined for Wassermann's reaction, and, if the result be doubtful, that the test be repeated in order that adequate treatment may be instituted. But we have no cause to despair even if Wassermann's reaction is assuredly negative.

The state of affairs is extremely unsatisfactory—groping in the dark, searching for the cause and rational cure of a complaint like vertigo, and then falling back on symptomatic treatment. Why is it that we find the cause of the vertigo to be so difficult to reveal? I think it is because we seldom see the patient in the vertiginous state; he has more often recovered than not, and when we do he is so distressed that a thorough examination of the labyrinthine apparatus and vestibular system seems quite impossible. Consequently his symptoms are treated, but not the cause.

Fortunately, through the last 16 years I have had many opportunities of seeing patients when actively vertiginous, both when their symptoms have been due to some gross disease of the ear or brain, and what is still more important, vertiginous when there was no obvious cause discernible, even after a general physical examination. We are all familiar with the latter class.

The vertigo masks other complaints. We have been led to suspect some labyrinthine disturbance; to treat this class of case rationally we must know something more of its precise nature. We see reason for believing it is not cardiac, gastric, renal, not due to local hæmorrhage, nor to local infection (in the obscure class I refer to).

Unilateral Eustachian Inefficiency as a Cause of Vertigo.

The cause, often so subtle to find, and consequently so often overlooked, though admitted as the cause when recognised,[3] is, in my experience, simply unilateral Eustachian inefficiency. It can be proved by looking at each drum while the vertiginous patient attempts to inflate his ears, and noting that one or both fail to expand. The disturbance caused by Eustachian inefficiency is better known to those who are familiar with the effect of passing through sudden changes of atmospheric pressure, as caisson. Divers know to their anguish the pain in ears caused by entering the compression chamber with a cold in the head, which prevents equalisation of pressure on the drums; giddiness, staggering, or vomiting may occur. High-flying airmen who return from atmospheric pressures of 360 mm. Hg on the drums of the ears know the necessity of "clearing" the ears by some procedure, such as "frequent swallowing" or by self-inflation by Valsalva's method. The Eustachian tubes are normally closed, except during the act of swallowing, when they should open for the fraction of a second and close again like the shutter of a camera.

---

[2] Proc. Roy. Soc. Med., 1917 (Otol. Sect.), Discussion on Vertigo.

[3] Dr. Peter McBride, Dr. Dundas Grant, Dr. Urban Pritchard, and others report isolated cases, in otological literature.

It is when the tubes fail to open through some inefficiency, such as is produced by congestion or swelling of the mucous membrane due to a cold or catarrh, or when blocked by tenacious mucus or by temporary engorgement of the blood-vessels which supply the pharyngeal end of the tube, that the regulating action fails. A too tight collar in some is known to produce the same result. Why is this mechanism necessary? Because, as I have shown from laboratory experiments, a sudden change of pressure from low to high or high to low in the normal labyrinth on one side, or an asymmetrical change of pressure through the two sides, sets up temporary vertigo with nystagmus and other forced movements which characterise vestibular disturbances.

Treatment.

What, then, is the treatment for the great majority of cases of so-called Menière's disease? Having scientifically excluded other factors, the treatment is directed to the Eustachian tubes. Continue to treat local catarrh and remove its cause, and train the patient to keep his Eustachian tubes free. Carry a Politzer bag, and if you intend to make sure of arresting an attack or series of attacks employ the Eustachian catheter. Do not despise it. Learn its uses accurately and carefully, for cases needing experience and practice are common. Only in cases of special difficulty need the physician despair. Are we, then, to regard bromides, iodides, purgatives, rest, and so on as erroneous measures? Far from it; their value is too well known, but their method of acting is not altogether clear. Is it possible that bromides diminish the reactivity of the individual to labyrinthine disturbances? Perhaps the iodides influence the naso-pharyngeal secretion of mucus and make it more watery, as in other parts of the air-passages. Quinine in minute doses, though possibly sedative to the vestibular system, just as large doses are irritative, may also derive its reputation from its anti-catarrhal action, for we know of certain persons, subject to winter head colds, who appear to derive immunity while taking minute doses of quinine daily without other drugs, or change of habits, residence, or mode of living.

We do not know with certainty how these drugs succeed and why they often fail, but I have attempted to suggest how they may sometimes succeed in restoring Eustachian tube efficiency. If this is a correct interpretation it enables us to understand the subtle relationship between the majority of cases of recurrent vertigo, commonly known as Menière's disease, and Eustachian tube obstruction or inefficiency.

FRACTURES OF TIBIA AND FIBULA: THEIR TREATMENT BY PLATING OPERATIONS.

BY C. FREDERICK STRANGE, M.R.C.S.,
L.R.C.P. LOND.,
MÉDAILLE D'HONNEUR DES ÉPIDEMIES; CAPTAIN, R.A.M.C.;
LATE SURGICAL SPECIALIST, NO. 1 CHINESE GENERAL
HOSPITAL, B.E.F., FRANCE.

DURING the past year I have had a very large number of fractures of the lower limb under my care at No. 1 Chinese General Hospital. This paper deals with 15 consecutive cases in which I have plated the tibia, and in some cases the fibula also. In all cases under consideration both these bones were fractured.

The hard work that fell to the Chinese Labour Corps behind the lines and at the bases and ports where munitions and stores were unloaded had exposed them to accidents of all kinds. No. 1 Chinese General Hospital had 2000 beds, it had the status of the usual general hospital in France, and in its equipment and general management left nothing to be desired save that all the nursing was done by Chinese male dressers. There has never been a matron and staff of nursing sisters. It is true that during the first six months the hospital was in existence we had no X ray department, but this was installed later, thus making the equipment complete. Before its installation all cases needing radiography were taken to Abbeville, ten miles away.

The injury in the cases to be described was severe, as in every case both bones were broken. In the great majority of the cases the fracture of the fibula was at about the same level as the tibia, being the result of direct violence, and in many instances the bones were badly comminuted at the site of fracture.

It is encouraging to note that in each of the 15 cases a perfect result was obtained, despite the absence of a highly trained nursing staff. All were cases of simple fracture due to direct violence, except perhaps one, in which the skin was broken at the level of the break; the wound did not communicate with the fracture, and operation was delayed until this was healed. I do not advocate plating of compound fractures. Experience in our military hospitals during the war is directly against this procedure unless under exceptional conditions.

Importance of Expert Technique.

It is now 25 years since Sir W. Arbuthnot Lane first introduced the then novel and revolutionary treatment of operating on cases of simple fracture and uniting the fragments in position by plates screwed into the bones. Since then many surgeons have adopted the practice in selected cases with varying results. Many have made hopeless failures through bad technique or lack of surgical skill, and consequently this treatment of fractures is frequently derided. But this series shows that, if the principles of aseptic surgery are scrupulously carried out and the operating surgeon understands the technique of bone plating, this method, far from being a failure, becomes an unqualified success.

Undoubtedly a very great deal depends upon the skill of the operating surgeon, and this method of treatment should only be adopted by those who possess that necessary gift. Many brilliant general surgeons, according to Lane, do not advocate the plating of simple fractures because they are not conversant with the technique of bone plating.

Desirability of Early Operation.

Speaking generally, the nearer the time of the operation to the date of the injury the better will be the result. It certainly makes the operation infinitely easier if it is performed before callus has been laid down. If the operation takes place within 14 to 21 days after the injury the ends of the fragments are clean, sharply defined, and when brought together dovetail into each other beautifully, so that the result is perfect, with no shortening of the limb and no stiff joints; in fact, a limb as sound and useful anatomically and functionally as the one unbroken.

For the first six months I was working at a great disadvantage in the absence of X ray installation at the hospital. This fact has, fortunately, not militated against the results of the first cases, which are in every way satisfactory. From personal observation of hundreds of fractures, especially of the tibia and fibula, where both bones are transversely broken and there is great displacement of parts, I have come to the conclusion that no other treatment offers the patient the same hope of getting a perfect limb, functionally and anatomically, as an early plating operation.

Treatment of Two Cases of Long Standing.

I have learned that in plating old-standing cases of fracture of both tibia and fibula, where there is mal-union with shortening of the limb, it is not sufficient to deal with the tibia alone; it is necessary to cut down upon the fibula, expose the fracture, and chisel through the callus *before* putting the plate on the tibia. Case 24330 shows this. In this instance I did not interfere with the fibula. The operation was undertaken four months after the injury, and there was strong callus formation both of tibia and fibula. I should have obtained a better result had I exposed the fibula and chiselled through the callus uniting it in the mal-position in which the radiograph showed it to be. This manœuvre enables more freedom of movement in getting the tibial fragments into perfect apposition, which is the most important consideration.

To get an ideal strong tibia it is necessary to have the lines of force conducting the body-weight in the same vertical plane, and not to have them transmitted to the lower fragment through a deflection, as in mal-union. This ideal can only be obtained by a method, such as a plate, which keeps the broken fragments in perfect apposition.

In only one case (No. 6724) had I to shave the broken ends in order to bring the fragments of the tibula and fibula into apposition. In this case there was excessive shortening (2½ inches) and the operation was not undertaken until eight months after the injury. There was no union of either bone. This was the more remarkable because at the same time the patient had sustained fractures of the right humerus, ulna, and radius. When he came under my care all these fractures were perfectly healed, with full use of his right arm. His left leg was encased in plaster, and on removing this I found the limb shortened as above with no union at all. There were pressure sores on the heel and over the lower end of the upper fragment of the tibia. The radiograph taken showed grave displacement of the bones, the ends being eburnated and rounded with no attempt at callus formation. He had not left his bed for eight months, as he was unable to put his foot to the ground. Operation was postponed till two months after the pressure sores were healed. Eventually the patient only had ½ inch shortening, which is very little considering the great displacement and the long time elapsing between the injury and the operation. When he had been on duty a month he met with another accident to his left leg, falling heavily over a tent rope in the dark. He was readmitted into the hospital under my care with his left knee-joint distended with blood, but the bones and the new union had stood the strain of the fall without giving way. I maintain that no other method of dealing with the fractures would have given such an eminently satisfactory result.

Of the whole series this is the one operated on at the greatest distance of time after the injury—namely, eight months, and yet the end-result has been all that could be desired except for the inevitable shortening.

The Technique.

A few observations about the technique employed, the incision, and the after-treatment may be of some interest.

The incision should be a long one—9 to 12 inches. The best position for the incision is a quarter of an inch external to, and parallel with, the crest of the tibia. This should be performed with one cut, which goes through skin and superficial and deep fascia, exposing the tibialis anticus, which is then gently separated from the tibia with a periosteal elevator. No vessels or nerves are encountered in this incision, and it gives access to as much of the tibia as need be exposed. It is a great mistake to make the incision too short, and there is no need to make it over the superficial surface of the tibia. Another incision over the fibula should be made if that bone has to be exposed. It is essential to have a complete set of Lane's special plating instruments, and another essential, in my opinion, is to have plenty of assistants; three are the minimum, and four are desirable. One is told off to hold the foot and to do nothing else, as very much depends upon this assistant carrying out the minute instructions of the operating surgeon. Lane's large long-handled curved periosteal elevators are now passed round the tibia from either side, completely exposing the fracture; the ends are seized with the special bone-holding forceps and the fracture brought out of the wound. The ends are cleaned and brought into perfect alignment and apposition, and held in place with another special forceps, which allows a plate to be placed over the fracture without again disturbing the forceps holding the fragments in place.

The Site of the Plate.

In every case the plate should be applied to the external surface of the tibia, which is as easily exposed as the antero-internal surface. Here the plate is screwed on and is tucked away between the tibia and the fibula, out of the way of all tendons passing to the foot.

A fairly long plate should be used, 6 or 8 inches long, with room for three screws on either side of the fracture. If the fracture is in close proximity to the ankle-joint shorter plates bent to the curvature of the tibia should be used.

In fractures involving the tibia 1 to 3 inches above the ankle-joint the incision needs to be carried downwards in front of the joint and the tendons of the tibialis anticus and extensor proprius hallucis drawn outwards. These tendons never need be severed. The upper part of the anterior annular ligament may need to be severed, but this is not important; it reunites and its function is not impaired.

Further Details.

The plate and screws should be kept in boiling water until they are wanted, and grasped by means of instruments. The operator should not touch the patient with his hands from the beginning to the completion of the operation. No vessels will need ligaturing; if any are cut they should be clamped with Spencer Wells, which can be removed before the wound is closed by Michel's clips, which are ideal for this purpose. Thus not a single ligature or stitch is used; in fact, frequently even with much exposure of the tibia not a single pair of Spencer Wells is required, as with careful technique not a single blood-vessel needing ligaturing is encountered. Moist eusol dressings are applied to the wound and the limb is firmly bound over cotton-wool. I prefer to keep the limb slung in a Thomas splint with a moderate amount of extension until the clips are removed 11 to 14 days after the operation. Six weeks later it should be difficult to find the incision. Passive movements of the knee- and ankle-joints are commenced when the clips are removed. After a month the limb should be put on to a back splint with a foot-piece.

Massage, if necessary at all, should not be commenced till two months after the operation. Usually it is not required at all. After three months, but not before, the patient may be allowed to walk, putting weight upon the limb. By then the callus uniting the bone is sufficiently strong to stand the weight of the body, although it may not reveal its presence in a radiogram. After four months the fractured limb should be as strong and useful as the good one, with no disability whatever, no shortening, and not a vestige of stiffness in any joint.

This sounds very ideal, but in all the cases described it was the result obtained, the only case of shortening being the one where the ends of the bones, eight months after the injury, had to be pared to give them approximating surfaces. If the patient is anxious to get about after a month he may be allowed up in a calliper splint, but it is better not to permit even this until two months after the operation.

In my opinion the reason that screws work loose is that weight is allowed to be put upon them before there is a sufficiently strong callus laid down; this is not strong under three months. The function of the plate and screws is not to bear or even transmit weight; it is simply a scaffolding to hold the fragments in apposition and correct alignment until Nature has supplied the new bone, which it always does in my experience. I have never seen a loose screw in any of my cases of tibial platings.

Details of Cases.[1]

CASE 986.—Admitted 7/2/18 with fracture of left tibia and fibula. Large piece of wood fell on the left leg causing transverse fracture of the bones just above the ankle-joint. Brought the same day from Dieppe. Radiograph showed great displacement of the lower fragments inwards.

18/2/18: *Operation.*—Tibia exposed by longitudinal incision along the outer side of the tibial crest. The fragments thoroughly exposed and isolated and easily brought into excellent apposition. The plate was first bent to accommodate itself to the outward slope of the tibia and screwed on, maintaining the broken fragments in apposition. Wound closed with Michel's clips. No vessels were cut or ligatured during the operation. Limb put up on back splint with foot-piece and side pieces.

1/3/18: Michel's clips removed; the wound perfectly healed; movements of knee- and ankle-joints carried out. 4/3/18: Daily passive movements of joints. 16/3/18: Radiographed; shows fragments in perfect apposition and the fibula also brought into good alignment. 17/3/18: Splints removed. 17/4/18: Getting about with aid of crutches. 18/5/18: Walking quite normally with no assistance from crutches or sticks, no discomfort of any kind complained of. 18/6/18: Radiographed; shows excellent callus formation with bone in perfect position. The fibula now is united with no displacement of parts. 22/8/18: Radiographed; it is now not possible to see where the break occurred, the fibula has come into perfect alignment and a new medullary cavity is in process of formation. 27/8/18: Discharged to duty. This has resulted in an eminently satisfactory way.

CASE 24330.—Admitted 29/11/17 with fracture of right tibia and fibula 4 in. above ankle-joint, having been knocked down by a motor lorry. The M.O. in charge of ward put him up in a box splint. Massage commenced 8/12/17; fragments apparently in good position. 17/12/17: Slight œdema of leg; no sign of callus formation. 10/1/18: Considerable œdema and tenderness over site of fracture. 14/1/18: Put up in a Thomas splint with extension. 25/1/18: Thomas splint removed. Patient cannot elevate leg from the bed, but can move his toes and flex his ankle. (At this stage patient came under my care.) 9/2/18: Radiographed; shows fragments in very bad position, greatly displaced laterally and inwards.

20/2/18: *Operation.*—Longitudinal incision 9 in. long on outer side of crest of tibia; bone exposed; callus broken down and chiselled away. Fragments brought into good apposition. Plate screwed in on outer surface of tibia, wound closed with Michel's clips; limb put up in a Thomas splint.

5/3/18: Michel's clips removed; wound completely healed; passive movements of knee- and ankle-joints commenced. 17/3/18: Thomas splint removed. 25/3/18: No shortening of leg; ankle-joint normal. 3/4/18: Radiographed; shows fragments of tibia in fairly good position, but it also shows that if the fracture of the fibula had been broken down at the operation the result would have been much better. The fibula being firm made it difficult to get the tibial fragments into the best position. 17/4/18: Getting up on crutches. 25/6/18: Radiographed; shows excellent callus formation. 5/8/18: Discharged to duty. Limb strong and free from pain or any discomfort.

CASE 59790.—Whilst at work accidentally knocked down, fracturing the left tibia and fibula. Admitted two months later with ¾ in. shortening of leg. 8/3/18: Radiographed; shows oblique fracture of the tibia at junction of middle and lower thirds, with much displacement of lower fragment outwards and fracture of fibula in upper third.

28/3/18: *Operation.*—Site of fracture in tibia exposed through longitudinal incision to outer side of the crest. The callus was chiselled through, the ends of the bone cleaned and brought and held in good apposition with much difficulty, owing to the shortening of the fibula. The plating was done three months after the accident at the special request of the patient. The callus was well formed, but not very hard. Wound closed with Michel's clips, and limb put up in a Thomas splint with extension.
